personal evolutionary success is not determined by the number of personal offspring one has, but by the number of common alleles in the population. Thus, cooperative behavior that may cause one to incur social costs is considered beneficial in that it promotes an investment in the well-being and reproductive success of one's kin. For this to occur, an individual must be able to accurately identify kin. Key indicators of kinship are phenotypic similarity and behavioral similarity. Indeed, we find that humans use facial similarity as a cue to increase prosocial behavior and to decrease sexual attraction, lending empirical support to Hamilton's inclusive fitness theory (DeBruine et al. 2008).

Self-concept is generally a stable characteristic, yet it may fluctuate based on social experiences (DeBettignies and Goldstein 2019). It is for this very reason that kinship is central to the self-concept, as kinship serves as an unfluctuating anchor. Twin and adoption studies demonstrate that genes rather than upbringing cause people to engage in social associations (Rushton 2009). Demonstrating these attributes as fundamental to the self-concept, not only do humans respond favorably to the positive actions of others but also to the phenotypic similarity of others (Parsons et al. 2016). Thus, kinship provides a stable template for the self-concept. Additionally, kinship provides this crucial information at a young age, when individuals are developing their own mental templates of the self. Children use these kinship cues during childhood to not only discern their relationship with others but also develop their own identity (Antfolk et al. 2014). These cues have been found to predict behavior later in life and thoughts about the self. Taken together, this suggests that kinship both prescribes our personal behavior and is central to the development of the self.

Modern Family

Traditionally the family has been regarded as the most basic form of kin. Changes in society over time have led to an increase in households that are not comprised of a traditional nuclear family. This

has challenged the traditional view that kin is defined by shared biogenetic substance (Hayden 1995). Both the traditional Darwinian conceptualization of kinship and cultural conceptualizations of kinship are integrated as the primary support system of individuals. As such, both assist with survival as well as psychological well-being (Shapiro 2014). This expanded notion of kinship develops at an early age. For example, infants are able to grasp social relationships. When observing a common adult comforting multiple babies, infants are able to recognize that there is a common association among babies who were comforted by the same adult, inferring that infants are capable of understanding some level of kinship in others (Spokes and Spelke 2017). This also suggests that when infants are forming their own early self-schemas, they are integrating those around them into those mental templates. Thus, from the moment one is born, one is establishing notions of kinship and using those notions to establish their own identity.

Conclusion

In organizing information about our world, humans develop distinct schemas. Some are about our own unique personality, and others center on our social identity. Kinship is central to both and, as such, central to our own self-concept. Kinship has evolved to provide individuals with unique information about themselves and those that would be beneficial for them to assist. In providing individuals with information about the self, humans are able to develop the self-concept. For it is these very interactions with those that we consider as our kin, biological or chosen, that allow us to see ourselves as both unique and yet simultaneously part of a larger collective.

Kinship Psychology Manipulations

Kristen Syme

Washington State University, Vancouver, WA, USA

Synonyms

Fictive kinship; Inclusive fitness; Induced altruism; Kin selection; Kin-cue manipulation

Definition

Kinship psychology manipulations in the context of suicide terrorism is a form of deception that effectively tricks individuals into acting altruistically towards non-kin as a result of the activation of kinship cues that over evolutionary history allowed individuals to decipher kin from non-kin.

Introduction

One evolutionary theory of suicide terrorism proposes that terrorist organizations manipulate followers into embarking on suicide missions in part by activating evolved kinship psychology. This theory of suicide terrorism is informed by kin selection (Smith 1964), a form of altruism based on Hamilton's rule ($rb > c$) where r is the degree of genetic relatedness, b is the reproductive benefits to related kin, and c is the cost to the agent (Hamilton 1963). Therefore, an organism should act altruistically if the reproductive benefits to its kin outweigh the costs of the act to the organism, thus increasing the organism's inclusive fitness. Kin selection demonstrates how traits that harm individual organisms can be maintained by natural selection (Liddle et al. 2011). Kinship psychology manipulation is a form of deception that effectively trick individuals into behaving altruistically despite the behavior not serving the reproductive interests of the actor.

Theory and Evidence for Kinship Psychology Manipulations and Suicide Terrorism

Kin recognition is a critical component of kin altruism. An organism must have the ability to calculate the degree of genetic relatedness (r) to a conspecific in order to determine whether to act altruistically; therefore, cues of genetic kinship must have evolved. According to Qirko (2004, 2009), hypothesized cues of genetic kinship among humans include physical proximity during development, shared phenotypic traits, and the use of kinship terminology (Alexander 1990; Fletcher and Michener 1987; Hamilton 1964; Sherman 1985). Applying these concepts to both suicide terrorism and lifetime vows of celibacy, Qirko predicted that institutions that solicit individuals for these practices would tend to (1) seek out recruits who are younger in age; (2) separate recruits from genetic kin; (3) endorse the use of kin referents between members; (4) encourage the use of markers that mimic shared phenotypes (e.g., uniforms or other identifiers); and (5) facilitate close proximity among the in-group members (2004, 2009, 2013). In fact, each of these predictions is supported by empirical data. Terror organization often recruit suicide attackers before they reach their twenties, recruits are separated from their genetic kin and trained in isolation from their natal families and communities, kinship terms are commonly used between members of these groups (Qirko 2004, 2009, 2013). The hypothesis that suicide terrorists are motivated by kinship psychology manipulations is distinct from hypotheses that posit that suicide attack produces tangible benefits to kin such as monetary gain (e.g., Blackwell 2006) (see Suicide as Kin-Directed Altruism).

Conclusion

Kinship psychology manipulations act on evolved mechanisms that over evolutionary time assisted organisms in distinguishing kin from non-kin. Some evolutionary theorists contend that kinship psychology manipulation is the primary vehicle

through which terror organizations convince adherents to forego their own reproduction and self-sacrifice for the benefit of the group. However, as Blackwell (2006) noted, many would-be suicide attackers pledge allegiance to the terrorist institution prior to the use of kinship cue manipulation.

Kinship Universals

- [Universal Aspects of Kinship](#)

Kissing

Christopher D. Watkins

Division of Psychology, School of Social and Health Science, Abertay University, Dundee, UK

Synonyms

French kissing; Mouth-to-mouth kissing; Romantic kissing

Definition

Research that examines the possible evolutionary function of kissing on the open lips/mouth as a custom during courtship or within a long-term pair bond.

Introduction

Romantic kissing is a custom documented in historical texts (Nyrop 1901), including several types of kiss described in the Kama Sutra of Vatsyayana approximately between the first and sixth century (Burton 1883/2006). Comparative perspectives also reveal analogies between romantic kissing and other coordinated courtship rituals in non-human species. This research, relatively new at the time of writing, examines the extent to which this form of romantic expression has a functional basis, given that it is observed widely across nations, tends to precede other forms of intimacy, and may influence attraction to one's romantic partner. This entry reviews the early accumulation of knowledge in this area and the evolutionary theory that underpins it.

Romantic Kissing: Theory and Data

Romantic kissing, according to the wider anthropological record, is observed in less than 50% of cultures in contrast to nonromantic kissing such as that between parent and offspring and romantic

passion which is regarded as a human universal (see Jankowiak et al. 2015 and other work by this author for discussion). Observational studies suggest that romantic kissing is accompanied by a rightward bias in head orientation (Güntürkün 2003) and, in a study of married couples in Bangladesh, is more likely to be initiated by men than women (Karim et al. 2017). Focusing specifically on mouth-to-mouth kissing (i.e., “French kissing”), Wlodarski and Dunbar (2013a) theorized that romantic kissing may function as (i) a mate assessment tool to assess putative cues to quality via close contact, similar to species that use gustatory and olfactory cues to regulate courtship behavior (Clowney et al. 2015), (ii) to gauge and maintain the quality of a long-term pair-bond, and (iii) to facilitate arousal prior to sexual activity, in light of the sensitivity of the lips and the potential importance of this precopulatory behavior for physical arousal and/or psychological pleasure (see e.g., Basson 2000 for discussion of the female sexual response cycle). None of these hypotheses were intended by the authors to be mutually exclusive to one another.

Using the mate assessment hypothesis as a framework, kissing may incur costs to health (e.g., Posse et al. 2017) which the “behavioral immune system” would be sensitive to (see related entries on ► “Disease Avoidance”). Thus, as a pathogen avoidance mechanism, cues to “quality” in a mate could be valuable to gather during courtship or in short-term relationship contexts more generally. Consistent with this first hypothesis, being perceived as a “good kisser” can enhance desirability as a short-term relationship partner (Wlodarski and Dunbar 2014) and kissing is considered more important, and more likely to influence attraction for women than men (i.e., the “choosier” sex), for choosier individuals of higher “market value” (i.e., attractive individuals) and in contexts where choosing a less healthy mate would be particularly costly (i.e., short-term relationships, Wlodarski and Dunbar 2013a). Of note, although some of these differences are small when examining the accompanying effect sizes, small differences in romantic behaviors and appreciation of intimate acts may still be of theoretical relevance when studying

relationship dynamics, if they have cumulative effects over time on how members of a couple communicate, navigate, respond, and interpret issues related to intimacy within their relationship. For example, even if differences in preference in this area are subtle, it may still translate into one member of the dyad communicating their satisfaction or dissatisfaction first. Secondly, when people are asked about what constitutes a “good kiss,” gustatory and olfactory cues are considered particularly important and women place greater importance on kissing in the very initial stages of a relationship when their progesterone levels are also low, a proxy for conditions related to high fertility (Wlodarski and Dunbar 2013b). Collectively, mate assessment may be an important function of mouth-to-mouth kissing.

Following the pair-bonding hypothesis, kissing would be expected to enhance relationship quality if it is a display of romantic attachment. Consistent with this line of reasoning, frequent kissing and satisfaction with kissing frequency in relationships is correlated with relationship quality, while having a partner who is a good kisser predicts relationship quality at twice the size of the relationship between sexual satisfaction and relationship quality (Wlodarski and Dunbar 2013b). Work to date thus suggests that kissing may be important both as a courtship custom and in maintaining stable long-term pair bonds. While this research does not support the role of kissing in facilitating arousal in specific relationship contexts (e.g., preferred at times preceding sex than at other times, Wlodarski and Dunbar 2013a), further work using more direct measures of arousal (i.e., compared to self-report measures) may shed light on the role of kissing in arousal and generate further discussion within sexology. Indeed, the components of a “good kiss” appear to reflect (i) sensory factors, (ii) technique, and (iii) arousal/contact (Wlodarski and Dunbar 2013b). Thus, kissing may be a fruitful topic for researchers of behavioral synchrony and also for sexual and health scientists, in light of the potential importance of arousal for lowering disgust sensitivity (see

related entries on ► [“Disgust”](#), and ► [“Pathogen Avoidance”](#)). Finally, as proxies for social complexity are thought to predict kissing prevalence in remote societies (Jankowiak et al. 2015) further cross-cultural work can shed light on the factors involved in the development of this romantic behavior in some cultures but not others.

Conclusions

Romantic mouth-to-mouth kissing is not a human universal; however, it is prevalent cross-nationally and is important during courtship and in long-term pair bonds. Further work in this area is of utility for sexual science and empirical work on well-being in romantic relationships, as are comparisons across cultures and species and in research on the developmental basis of intimacy and romantic customs.

Lactose Intolerance

James R. Donovan
Nipissing University, North Bay, ON, Canada

Lack Clutch Size

- [Optimal Clutch Size](#)

Definition

Lactose intolerance commonly, but not universally, is defined as the inability to digest lactose (found in milk and other dairy products) that often results in symptoms which cause individuals to experience discomfort or pain (Deng et al. [2015](#); Amiri et al. [2015](#); Sahi [1978](#); Misselwitz et al. [2013](#)).

Lack of Respect

- [Derogation of Rivals](#)

Lacrimation

- [Crying](#)

Introduction

Milk and other dairy products are often fed to newborn children during infancy to provide nutrients that assist in growth and development. However, not all humans have the ability to digest milk, specifically a component in milk and dairy products called lactose, without experiencing pain or discomfort. The inability to digest lactose is due to the individual lacking the enzyme lactase that

Lactation

- [Breast Feeding](#)
- [Breast Milk Composition](#)

is found in the intestine that allows lactose to be broken down (Deng et al. 2015; Amiri et al. 2015). Some common symptoms of lactose intolerance are flatus, abdominal pain, bloating, stomach rumbling, diarrhea, nausea, and constipation, among others (Deng et al. 2015; Szilagyi 2015a; Mattar et al. 2012; Misselwitz et al. 2013). Milk provides a variety of nutrients that the lactose-intolerant individual has difficulty consuming. As discussed below, the inability to digest lactose may have been particularly problematic during times of famine and migration through regions in Europe and Africa. Milk and other dairy products were a quick and easy way to gain nutrients; however, for those who could not digest lactose, it meant those individuals were at a nutritional disadvantage (Szilagyi 2015b; Misselwitz et al. 2013). In today's era lactose intolerance is less of a disadvantage or threat to an individual's health because the availability of food and alternative options to milk allow individuals to get the nutrients they require, making the consumption of milk and dairy less important. In addition, the diagnosis and treatment of being lactose intolerant is commonplace and widespread throughout the world, allowing those individuals to understand the issue early on and to more easily manage being lactose intolerant.

Diagnosis

Lactose intolerance is usually diagnosed by one of three ways, the most common is by conducting a hydrogen breath test that measures the amount of hydrogen that is produced in the small intestine from lactose not being digested (Heaney 2013). The second method for testing lactose intolerance is via biopsy of the duodenum of the intestine where the level of lactose can be measured and the rate of lactose digestion can be evaluated to determine if lactose is being broken down (Mattar et al. 2012). The other method to diagnose lactose intolerance is through genetic testing via blood analysis. Each method has drawbacks, and none is considered a gold standard in and

of itself. However, the hydrogen breath test is the most common for its efficiency and easy application (Deng et al. 2015; Amiri et al. 2015; Mattar et al. 2012).

Treatment

Lactose intolerance is usually treated by initially reducing all consumption of dairy/milk products, especially those that contain lactose. This initial reduction of lactose is meant to improve symptoms of the disorder so the individual can begin to feel better (Amiri et al. 2015; Misselwitz et al. 2013). Depending on the individual and the severity of symptoms, dairy and milk products are slowly reintroduced into the individual's diet (Szilagyi 2015a; Amiri et al. 2015). If the individual experiences severe symptoms, non-lactose-based dairy and milk products can be used to help regain calcium in the diet without the risk of symptom flare-up. Complete reduction of dairy- and milk-based foods is not ideal nor is it recommended by clinicians. Rather, lactose intolerance is treated with a careful regime of dairy and milk products that can be easily and safely digested to allow the individual to maintain a healthy diet without having to experience pain or discomfort. In fact, even those with lactose intolerance can safely consume around 12–18 g of dairy/milk containing lactose without experiencing any symptoms (Mattar et al. 2012; Misselwitz et al. 2013; Heaney 2013). However, consumption of more than 18 g of dairy/milk containing lactose within a single sitting can produce painful or uncomfortable symptoms (Mattar et al. 2012).

Biological Details

Lactose is a disaccharide consisting of galactose bound to glucose and is often found within dairy products like milk, cheese, and yogurt (Heaney 2013; Deng et al. 2015; Misselwitz et al. 2013). Within milk is lactase, and it is broken down by lactase, an enzyme, within the small intestine

(Heaney 2013; Deng et al. 2015). However, our production of lactase begins to decline as we age and begin to wean off of feeding in infancy, with production of lactase decreasing to about 10% of its original quantity around 5–10 years of age (Deng et al. 2015; Szilagyi 2015a; Amiri et al. 2015; Sahi 1978; Misselwitz et al. 2013). This reduction in lactase affects roughly two-thirds to three-quarters of the world's adult population (Deng et al. 2015; Amiri et al. 2015). For some individuals the production of lactase reduces to even lower levels, causing an intolerance to any food that has lactose within it (Deng et al. 2015). When lactose is not broken down properly in the bowel, the small intestine begins to break down and ferment the lactose, and the result is the production of gases, primarily hydrogen, carbon dioxide, and methane (Deng et al. 2015; Misselwitz et al. 2013; Heaney 2013). This production of gas can lead to a variety of symptoms including abdominal pain, bloating, stomach rumbling, diarrhea, nausea, constipation, loss of concentration, muscle and joint pain, mouth ulcers, and urinary difficulties (Deng et al. 2015; Szilagyi 2015b; Mattar et al. 2012; Misselwitz et al. 2013; Heaney 2013).

Lactose intolerance and its symptoms are influenced by several variables including the amount of lactose consumed, gut transit time, ingestion with other dietary components, small bowel bacterial growth, and also composition of the enteric microbiome (Deng et al. 2015; Szilagyi 2015a). However, the incidence of lactose intolerance is not equal across races and geographic regions in the world. Next, the history of lactose intolerance and its recent development will be highlighted.

History

Humans have had the ability to consume and digest milk as infants and children throughout history. However, previously in history as we have grown up, our ability to produce lactase to break down the lactose in milk has turned off as

we approached adulthood (Burger et al. 2007). It is speculated around 10,000–100,000 years ago, our ability to digest lactose in adulthood emerged (Szilagyi 2015b; Misselwitz et al. 2013; Burger et al. 2007). A possible reason why lactose digestion emerged around this time is because this is the point in human history when Northern Europeans and some regions of Africa and the Middle East began to use milk to deal with famine (Sahi 1978; Swagerty et al. 2003). Famine occurred due to harsh weather conditions such as long winters in Northern Europe and extreme heats with lack of rainfall in Africa and the Middle East to sustain farming (Szilagyi 2015b; Swagerty et al. 2003). As a result of the inability to farm in these regions, individuals began to start consuming milk to survive. However, many adults still did not have the ability to properly digest lactose and milk, allowing for natural selection to occur. Those individuals who were able to consume milk and survive famine lived, however, those who could not consume milk would have either succumb to famine or likely experienced extreme pain from consuming milk in order to survive (Swagerty et al. 2003; Burger et al. 2007). By Consuming dairy and milk in order to gain the necessary vitamins to survive, our bodies had to adapt and learn to digest lactose (Szilagyi 2015b; Misselwitz et al. 2013). However, not every race and culture underwent this adaptation, and as a result, some populations have a higher incidence of lactose intolerance than others.

American Indians and Asians have the highest rate of lactose intolerance, and up to 80% of Black, Arab, and Latino individuals experience lactose intolerance, whereas the lowest prevalence is detected in northwestern Europeans (Amiri et al. 2015; Deng et al. 2015; Sahi 1978; Misselwitz et al. 2013; Heaney 2013). This difference in racial categorization for those who can and cannot digest lactose provides circumstantial evidence for the proposed geographic and environmental hypothesis for the development of lactose intolerance and digestion (Szilagyi 2015a). Those races and geographic locations within the world that received adequate sunlight, weather

conditions to farm, and received their calcium intake through other food products did not need to consume milk and develop the ability to further digest lactose beyond infancy (Szilagyi 2015a; Misselwitz et al. 2013). As a result of these historical events, it has allowed certain racial groups and geographic regions to be able to digest lactose in milk and force other groups and regions to adapt without the consumption of milk.

Conclusion

Lactose intolerance affects thousands of individuals a year and understanding the mechanism and history of lactose intolerance is integral to understanding how our health and evolution adapts and functions. Our ability to drink milk and consume dairy products is not simple, even though from birth we have evolved to consume breast milk to provide the necessary nutrition to survive as infants. In this chapter, human history, bodily functions and other human attributes have been shown to be more complex than previously thought. It is almost with certainty that seemingly normal activities of the body will reveal different functions and complex histories that question our understanding of what we have developed over millions of years. Lactose intolerance provides us with a small insight into how our body has evolved and why the consumption of milk and dairy is not beneficial to humans as we age because of our adaptation throughout history and should be used as a ideal and straightforward example of how evolutionary adaption for humans can be small but significantly impact how we live.

Definition

The tendency for humans to favor certain landscapes more than others and the theories developed to explain those tendencies.

Introduction

Humans, like all living things, live within an environment. Although that environment contains a wealth of biological and physical elements, ranging from the very small such as radiation and microorganisms to the very large such as geological formations and climate, humans have evolved to perceive only a fraction of these features. Arguably the most highly salient environmental element for humans is other humans, and people spend a disproportionate amount of their time attending to other people. However people also take notice of other things in their surroundings as well. The general term for all these other nonhuman, perceptible things is the *landscape*. People are aware of the physical elements of their landscape such as whether the shape of the land is flat or mountainous, the presence or absence of human-made structures such as buildings, fences, or bridges, and whether or not various forms of water such as rivers, lakes, ponds, or the sea are present. Humans also pay attention to the living elements of landscape, including the presence and density of different types of

vegetation such as trees, grass, or bushes, as well as the presence (or potential presence) and type of domestic or wild animals. Even transitory elements of the landscape are noticed, such as lighting, cloud cover, and weather conditions. At one point in human history, having a keen awareness of all these landscape elements would have been essential since the presence of particular plants or animals, sheltering qualities of a landform and access to potable water would have been fundamental to daily survival. However for the vast majority of humans alive today survival is almost totally a function of human-to-human interactions. As a consequence, most landscape elements, particularly those considered *natural*, are frequently viewed as mere backdrops to life, niceties rather than necessities.

Or so, most people think. In fact, landscapes still represent important dimensions of survival, even if the role they play are more subtle these days. And despite the fact that the presence or absence of particular vegetation or water forms no longer directly impact daily survival, people appear to not just be aware of these various landscape elements, they appear to prefer some more than others. The question is why? It is easy to understand why a person might prefer a particular type of vegetation if their life depended upon being able to travel across or harvest that vegetation for food, but what difference would it make to a person working and living in a city who makes their living as a banker? Even more intriguing is that in general, not only do humans seem to prefer some kinds of landscapes more than others but that these preferences appear to cluster around a relatively few types of landscapes and landscape elements. The most obvious way this convergence in preference is apparent is in the striking similarity in human-made parklands around the globe.

Human Landscape Preferences

One approach to understanding human landscape preference has been through the analysis of historic, worldwide patterns of “pleasure” garden design, i.e., gardens designed for aesthetic rather than utilitarian purposes. The idea being that

when unconstrained by budget or necessity, people would create landscapes that approached some optimal level of preference. One would assume that cultural tastes and traditions would vary considerably, but surprisingly large gardens and estates worldwide reveal some remarkable parallels in the use and organization of certain landscape elements (e.g., Jellicoe and Jellicoe 1975). Particularly in large gardens and estates, where aesthetic preferences could most easily be expressed, park-like settings of short grass and scattered trees have consistently emerged. The English landscape tradition, as typified in the work of “Capability” Brown, is one of the most familiar examples, where random placement of trees gathered in clumps are dispersed throughout an open field. Others have investigated landscapes in Western art (Appleton 1975) and calendars (Dutton 2003) and found a similar preponderance of scenes showing expanses of short grasses punctuated by scattered clumps of trees. In general appearance, all of these created landscapes converge toward a common landscape form, what is biologically called a savanna.

Savannas are ecosystems characterized by the trees sufficiently widely spaced so that the canopy does not close. The open canopy allows sufficient light to reach the ground to support an unbroken herbaceous layer consisting primarily of grasses, grading into either open plain or woodland. Savannas occur worldwide, with the largest occurring in subtropical or tropical regions. Two factors common to all savanna environments are rainfall variations from year to year, and dry season wildfires. Interestingly, recent evidence suggests that many indigenous peoples in both the Americas and Australia artificially created savanna through annual controlled burning (cf., Lentz 2000; Ward 2009).

Research by Falk and Balling (1982, 2010) has specifically shown a strong human preference for savanna-like environments. Additional support for these findings comes from studies that show strong preferences for landscapes containing open meadows surrounded by woods (Zube 1976), and forests are most strongly preferred whether there is little underbrush and an abundance of grass cover (Schroeder 1991).

However it is not just the general gestalt of savannas that appears to be preferred but also the shapes of major elements within them, including and specifically the trees. Orians (1980) demonstrated that horticulturists and landscape designers in Japan have tended to modify the phenotype of native tree-forms toward those found among trees existing in savanna environments. In a crosscultural study of tree preference (Oriens and Heerwagen 1992), subjects from three countries rated as most attractive those trees in which canopies were relatively dense and trunks bifurcate low to the ground. These characteristics of tree-form typify those found in the East African savanna. Sommer and Summit (1995) found consistent findings, with preference for large canopies and small trunks. A later study of tree species preference and context, Summit and Sommer (1999) found that the acacia-type tree-form, typical of the African savanna, was preferred over oak, conifer, palm, and eucalyptus.

In addition to savannah-like elements like short grass and scattered trees, research has consistently identified other specific natural features that increase the attractiveness of landscapes, in particular water elements. Many studies confirm that water is a highly preferred part of any natural scene, and it is not just the amount of water that is significant – clarity and freshness seem at least as important. Mountain lakes and rushing water, especially waterfalls, are extremely well-liked, while swampy areas or water covered with algae bloom receive low rating (Herzog 1985).

Sociocultural Perspectives on Landscape Preference

Like most human preferences, it can be argued that human landscape preferences is best understood as a social and cultural construction (John-Steiner and Mahn 1996); the passing on of aesthetic ideals and social conventions passed on from one generation to the next through human culture. This view of the world, which assumes that all human behaviors are the products of our culture and history, has a long history in the humanities and anthropology but has become

reinvigorated amongst psychologists with the rediscovery of the writings of Vygotsky (cf., John-Steiner and Mahn 1996). And there is certainly evidence to support this view.

According to Nassauer (1995), not only do cultures change the nature of landscapes through various practices such as agriculture or even hunting and gathering, but culture itself is embodied in landscapes. By this she means the humans are inseparably bound to the landscapes they inhabit through their cultures. Hence people from different cultural conventions and customs perceive landscapes in different ways, which directly affects what people notice, find interesting, and prefer about the landscape. People typically assume the prevailing norms of their social/cultural group, believing that a yard, a park, a field, or a forest should look a certain way without questioning the necessity of that appearance (Nassauer 1995). One need go no further for evidence of the cultural influence on landscape preference than the dramatic changes in attitudes toward *nature* and *wilderness* evidenced in modern society over the past 100+ years (e.g., Eisenberg 1998).

At a more fine-grained level, perhaps the most compelling evidence for the role of sociocultural factors in landscape preference is the critical role that familiarity plays. At least amongst adults, living within a landscape appears to result in heightened preference for that landscape (Balling and Falk 1982). For example, in a study of college students, Lyons (1983) found that preferences were highest for the most familiar biome. Subsequent, crosscultural studies reported similar findings, with high correlations between groups in their preference for varied landscapes, with familiarity accounting for much of the variance (Herzog et al. 2000). Herzog and colleagues replicated the earlier study by Kaplan and Herbert, but included a broader sample of settings and examined several subcultural groupings. Familiarity once again emerged as a significant predictor of preference and is consistent with our earlier thesis that preferences can be modified by experience and enculturation. Other seemingly socially and culturally influenced factors beyond familiarity also seem to contribute to preference. For

example, not just familiarity but experience and education (Balling and Falk 1982; Lyons 1983) can play a role in landscape preference. And beyond these findings, no study of people's affinity for different landscapes has ever found complete unanimity of preference. In other words, people do vary in their preferences and those variations almost certainly arise from personal experience as molded by social and cultural forces. However the consistent finding that children across cultures share similar preferences, independent of their cultural background (e.g., Falk and Balling 2010; Newell 1997), suggests that some aspect of landscape is likely innate.

An Evolutionary Psychology Perspective

The perspective that sees landscape preference as a by-product of human evolution has been advocated by a wide range of psychologists. According to this view, human preferences have developed because they have been crucial for human survival as individuals and as a species. These preferences do not appear to be random, in almost all cases these landscape features are exactly the ones which would have offered a good combination of safety and necessary resources to early humans. And particularly related to the seeming preference for savanna-like environments, preferences appear to converge on landscape features that figured prominently in the evolutionary history of human-like organisms in Africa some 1–4 million years ago – favored are places that could support a bipedal African primate's hunting and gathering and basic needs such as evidence of potable water and shelter and refuge from both predators and the elements.

The belief that human biology and behavior were significantly molded by the adaptations of humanity's early ancestors evolved in order to survive in African savanna-like environments were initially supported by a series of major hominid fossil discoveries in southern and eastern Africa during the early part of the twentieth century. The fossil evidence of the associated fauna and flora led anthropologists to the inference that the evolution of modern hominins was guided by

the significant warming events at the end of the Pliocene which resulted in significant changes in available habitats throughout Africa. The increase in aridity was thought to have propelled early hominins away from the comfort of tropical habitats, habitats still occupied by humanities closest primate relatives, into the more hostile habitat of the savanna. This view was challenged at the end of the twentieth century by subsequent research (cf., Foley 1996) which suggested that the landscape of human evolution may not have been exclusively savanna, but rather a mosaic of environments including grasslands, savanna, open and closed forests. However, new research and new analytic tools are once again tilting scientific thinking back toward a savanna hypothesis.

To get a better idea of the environments in which the human lineage evolved, scientists recently analyzed prehistoric soils associated with significant hominid fossil finds for clues about the likely vegetative pattern that existed at the time of fossilization (Cerling et al. 2011). By analyzing the ratio of carbon isotopes remaining in the soil of 1300 soil samples associated with hominin fossils, investigators were able to more reliably extrapolate as to the nature of the ancient vegetation that these ancient hominins once lived in. Researchers found that more than 70 % of the fossil sites were revealed to be savanna-like environments with less than 40 % tree cover. Less than 1 % of the ancient soil tested reflected sites where tree cover exceeded 70 %, which would have made the area a forest. While many scientists think East Africa was forested before 2 million years ago and savannas emerged only afterward, the findings of Cerling et al. (2011) suggest that during the development of bipedalism about 4 million years ago, that is, walking on two legs, savannas were present, even predominant. Thus, savannas appeared to be critical throughout the period of human evolution; seemingly wherever human ancestors were found, there is evidence those ancestors resided in open habitats similar to today's African savannas.

Based on the above evidence, it can be reasonably inferred that semiarid African savanna is likely the ancestral environment in which much of human evolution appears to have taken place.

An important choice for any mobile organism is selecting a good habitat to live in. Thus humans are argued to have a strong modern-day aesthetic preference for landscapes which mirror the attributes of what would be a good late Pliocene/early Pleistocene Afro-Eurasian savanna – a habitat characterized by both open and wooded areas, with trees with broad crowns and branches at a suitable height for climbing and taking foods, a habitat possessing readily accessible potable water and marked by features encouraging exploration such as the beginnings of a game track or a curving riverbed suggesting the possibility of game animals. This idea is not as far-fetched as some might assume. Humans, it seems are far from the only living thing to show distinct preferences for particular landscapes. In fact, species-specific habitat (landscape) preferences are the rule amongst animals of all kinds.

Most biologists would agree that habitat preferences are adaptive, since fitness is likely to be higher in a preferred habitat (Rausher 1984). Natural selection would maintain habitat preferences to the degree that they have a genetic basis, in fact the ability to distinguish and select among habitats is arguably one of the most evolutionary significant traits any organism can possess (Jaenike and Holt 1991; Rausher 1984). A wide variety of investigations have found evidence that vertebrate habitat preferences are at least in part, genetically determined (cf., Falk and Balling 2010). One early study showed that distinct, genetically determined, habitat preferences can exist even within races of a single mammalian species. More recently, research using biochemical markers was able to distinguish between the different alleles for at least one of the genes linked to habitat preference in two closely related species of toads. Previous studies have also identified the genes responsible for habitat preference in several insect species though even in insects there is evidence of learning (Segura et al. 2016). Hence a growing body of data supports the fact that a complex behaviors such as habitat preference can be at least partially genetically determined and that a wide range of organisms, including vertebrates of all kinds, possess these genetic traits.

Landscape Preference Factors

Following on the idea of an innate genetic predisposition toward landscapes, a variety of investigators have developed theoretical frameworks that attempt to dissect landscape preference into predictive variables. Particularly notable amongst these theorists are Jay Appleton (1975), Roger Ulrich (1977; 1983), and Stephen and Rachel Kaplan (1989). Among the earliest models was Appleton's prospect refuge theory. Appleton's initial work was based on an analysis of landscape painting (1975) which he found to consistently include similar landscape elements – depictions of low shrubs and clumps of trees divided by open spaces. He argued that these landscapes offer an attractive combination of *prospect* and *refuge*. Open spaces provide an opportunity for *prospect*, the ability to detect potential hazards – to see, whereas the low shrubs and clumps of trees provide *refuge*, places to hide and escape – to not be seen. Appleton suggested that humans have an affinity for settings that exhibit savanna-like characteristics, but he was careful not to suggest that there exists an optimum landscape preference since the idea of “optimum” implies that human needs are the same at all times. On the contrary, humans have varying requirements at different times, which effect how they interact with their environment. A more specific hypothesis of landscape preference stems from “prospect-refuge theory,” which predicts that within a given landscape preferred locations are found at interfaces between prospect-dominant and refuge-dominant areas. These vantage points combine unimpeded visual prospects with a ready opportunity for concealment and/or withdrawal to a safe refuge. Thus a treeless landscape is less visually attractive than a habitat containing isolated trees that can provide opportunities to hide or escape from potential predators.

Ulrich analyzed informational qualities of various settings and identified five significant variables: *focalcity*, the degree to which a scene contains a focal point or area that attracts the viewer's attention; *ground surface texture*, the perceived homogeneity or heterogeneity of the landscape; *depth*, the ability to see across

distances; *mystery*, the degree to which you can gain more information by proceeding further into the scene; and *complexity*, the degree to which a landscape is perceived to be rich and intricate. Ulrich built on earlier studies of visual preference which focused on complexity as the significant mediator of visual preference. These studies discovered an optimal range of preferred complexity in the visual field. In particular, results showed that visual preference was an inverted U-shaped function of increasing complexity. Stimuli judged to be of intermediate complexity were the most preferred, but for natural landscapes the effect was weak. Although Ulrich and other investigators found support for dimensions beyond complexity influencing landscape preference, Ulrich himself (1977) argued that the most powerful single variable was actually *mystery*. The presence of this factor heightened attractiveness irrespective of the ranges of the legibility variables. This model illuminated the importance of informational determinants but in order to create a more complete model, according to Ulrich the effects of color, water, and other ephemeral landscape elements such as clouds and sunsets should be added.

Like Ulrich, the Kaplans argued that the long-term survival of a highly knowledge dependent organism like hominins would need to depend upon acquiring and processing information about landscapes quickly and efficiently. According to the Kaplans (1989) people and their ancestors should have preferred settings that (1) make the acquisition of landscape information relatively easy and nonthreatening and (2) convey the notion that additional information can be acquired if the setting is explored. Thus, according to the Kaplans, understanding a landscape, which is the comprehension or making sense of the scene, should be predicted on information the needs of what he called *coherence*, landscape scenes where the elements are distinctive and easily identified, and *legibility*, the degree to which different landscape parts fit together, providing a sense of order and assisting in directing attention. While exploration needs should be predicated on a landscape's *complexity*, what a landscape offers in terms of the many different kinds of distinct elements present, and *mystery*, whether or not a new landscape

promises the opportunity for the viewer to go deeper into the landscape. These four dimensions, collectively known as *informational variables*, might refer to what is immediately perceptible, or might refer to what might be perceptible if one moved to another location. Although similar to Ulrich's model, the Kaplans' model has been the most widely used and cited. Considerable evidence over the years has found support for the relationship between each of the Kaplans' four informational variables and landscape preference (see review by Stamps 2004). However a recent meta-analysis of the Kaplan's model by Stamps (2004) failed to conclusively find a consistent relationship between landscape preference and any of the four factors.

Conclusion

Much of the research presented shares an underlying conceptual framework rooted in a Darwinian evolutionary view of landscape preference. Overall, the results reported here suggest there does appear to be strong evidence in support of the basic contention that humans possess some kind of genetically-based, innate landscape preference, particularly for savanna-like settings similar to those in which ancestral African hominins lived and evolved.

However, even if there is an innate basis to landscape preference, whether specific to key features of savanna-like environments like short grass and scattered trees with broad crowns and low branches or generalized as suggested by Appleton's (1975) ideas of prospect and refuge or based on psychological constructs such as Ulrich's (1977) five factors theory or Kaplan and Kaplan's (1989) coherence, legibility, mystery, and complexity theory, it is highly likely that there is more to the story than merely genes. To begin with, recent breakthroughs in genetics and biochemistry suggest that something as behaviorally complex as a visual preference for a landscape must involve multiple genetic loci, suites of epigenetic phenomenon, as well as behavioral and cultural elements (cf., Jablonka and Lamb 2014). Accordingly, the role of psychological factors such as perceived coherence, legibility,

mystery, and complexity as well as cultural sensitivity to the specific affordances of the visual environment are as likely contributors to landscape preference as are genetic loci connected to attraction to water and trees capable of being climbed.

However there is also strong support for the idea that cultural factors as well life experiences also can and do modify landscape preferences. Individual preference generally reflects both macroscale enculturation processes as well as more microscale factors such as social pressure and personal history. Collectively, the research suggests that landscape preference is a complex amalgam of factors, with innate preferences forming a foundation which is then overlain by both socio-cultural and personal experience factors.

In conclusion, the research summarized here provides additional support for the view that human behavior represents an ongoing and inherently complex interaction between human evolutionary history, human social and cultural history, and personal lived experience. Collectively these forces act upon individuals to shape a wide array of both observable and invisible traits and behaviors ranging everywhere from physical features, such as human posture, brain size, and diet, to complex behaviors and preferences, such as aesthetic preference for landscapes. Although human behavior is nearly always individually idiosyncratic and typically culturally diverse, there are times when human evolutionary history significantly restricts the extent of that idiosyncrasy and diversity. Human landscape preference appears to be one of those times.

Landscape Preferences: Climate and Weather

Kevin Bennett

Department of Psychology, Pennsylvania State
University, Beaver, Monaca, PA, USA

Introduction

The study of human behavior across diverse environments is certainly not new – this tradition dates back centuries – however, recent research has shed new light on the evolutionary forces that are associated with particular landscape preferences. Collectively, the research summarized here supports the idea that elements of the landscape, including climate and weather, interact with individual psychological processes.

Landscapes, Climate, and Weather

Variation in landscape, climate, and weather all have an impact on the organization of psychological phenomenon. Some cities, towns, and regions may have a geography that is more accommodating for some personalities than for others. Oishi et al. (2015) reported in a multi-study paper that when people wanted to socialize they preferred the ocean over mountains, but overall, mountain-lovers were more introverted than ocean-lovers. The introversion-extroversion disparity was further assessed using photographs of mountains and oceans. Part of the difference can be explained by extroverts' perception that they would have to put forth greater effort to enjoy themselves in the mountains. Extroverts believe that they will have an *easier time* having fun at the ocean.

An analysis of non-students showed that residents of mountain regions in the U.S. were more introverted than those living in flat states. Also, in a clever experimental test, the authors sent participants out to flat open areas or secluded wooded areas. The environment did not cause changes in

personality scores, but introverts were happier in the secluded area than in the flat terrain.

The human tendency to classify individuals as either “ingroup” or “outgroup” can be demonstrated along a continuum. At one end, *individualists* are motivated more by the boundaries between ingroups and outgroups compared to *collectivists* at the other end of the spectrum. The climato-economic theory (Van de Vlier and Yang 2014; Van de Vlier 2011) proposes that collectivism may be an adaptive solution to the existential problem that atmospheric climate can cause human death. They suggest that financial resources enable people to cope with the harsh climate demands of winter and summers. In a study that included measures of ingroup love and outgroup hate across 85 nations, they found that more demanding climates are correlated with stronger collectivism in relatively poor countries but weaker collectivism in relatively rich countries.

These data suggest that economic prosperity influences the impact of atmospheric climate on collectivist culture in that monetary resources enable people to cope with climatic demands of winters and summers. Climate and environmental pressures give rise to solutions that lead to geographical variation in cultural value systems. Collectivism is promoted in countries with demanding climates and economic difficulties. The analysis indicates that the driving force behind the process is ingroup love more so than outgroup hate. The authors argue further that the climato-economic explanation does a better job of accounting for the variance in ingroup-outgroup bias compared to theories of parasitic disease burden.

There is evidence that physical topography also plays a role in building culture and the development of value systems. In frontier regions with formidable terrain levels of individualism are higher than less menacing and more cultivated regions (Conway et al. 2014). Over time, this type of demanding environmental niche likely attracted tenacious individuals with personality traits conducive to surviving in such harsh habitats (i.e., independent and individualistic people).

Other research has concentrated on the effect of ecological stressors (climate stress, pathogen stress, and frontier topography) on vertical and horizontal governmental restriction (Conway et al. 2014). Vertical restriction describes a condition in which select individuals impose asymmetrical laws on others, while horizontal restriction involves laws that restrict most members of a society equally. Across three studies, the authors validated the measurement of restrictions and concluded that ecological stress creates opposing pressures that simultaneously push freedom in two different directions. Ecological stressors tend to inspire more vertically restrictive societies and less horizontally restrictive societies.

Weather and Climate on the African Savanna

There is considerable evidence that humans generally prefer savanna-like landscapes like those found in our ancestral past (Orians 1986). The Environment of Evolutionary Adaptedness (EEA) is the ancestral environment to which a species is adapted, or the set of selection pressures that shaped an adaptation. A central premise of evolutionary science is that forces in our distant past helped make us who we are today. The EEA refers to a group of selection pressures occurring during an adaptation's period of evolution responsible for producing the adaptation (Tooby and Cosmides 1992). A selection pressure can be any factor in a population that impacts reproductive success. Physical, social, and intrapersonal pressures from our ancestral past help to shape our current human design because all animals have heritable variations that are selectively favored or disfavored in accordance with reproductive success (Buss 1995). Each adaptation has its own EEA, or set of adaptive problems, that shaped it over evolutionary time.

According to the savanna hypothesis (Orians 1980, 1986) current habitat biases were shaped by selection pressures in our ancestral past. The theory argues that natural selection favored preferences, motivations and decision rules that attract

us to resource rich environments over resource poor environments. Two perspectives are helpful in addressing evolved responses to landscapes, one spatial and the other temporal. The spatial frame of reference points out three stages of habitat selection: *selection*, *information gathering*, and *exploitation* (Orians and Heerwagen 1992). The temporal dimension concerns short-term and long-term habitat variation in critical survival factors (e.g., weather patterns and seasonal transitions).

The second layer of the savanna hypothesis involves decision making over different time frames (Orians and Heerwagen 1992). Light availability and weather patterns are two time-related factors that impact choices. Long shadows at the end of the day may elicit the desire to set up campsite instead of continuing to move through the environment in darkness. Likewise, daily weather issues can force one to seek shelter quickly. Dark clouds, winds, thunder, and lightning are cues that may initiate the decision-making process.

Along with daily fluctuations, humans are sensitive to environmental changes on a seasonal scale. In general, natural selection favors traits that maximize benefits and minimize costs. People will show preferences for long term signs of robust prosperity because the algorithms that make habitat related decisions were shaped over time in response to specific positive and negative features of the environment. Indicators of harvest, such as fruit, budding flowers, and verdure, are favored over bare trees and impoverished fields.

A number of studies exploring landscape preferences have found support for the savanna hypothesis. For example, participants from Australia, Argentina, and the United States show a preference for savanna-like trees (Orians and Heerwagen 1992). In hospitals, patients who viewed trees outside the window recovered more quickly (Ulrich 1984), and bringing flowers increases optimism and improves the rate of recovery (Watson and Burlingame 1960). When placed in uncertain and stressful situations, individuals who viewed pictures of nature scenery showed less physiological distress (Ulrich 1986).

Research looking at over 900,000 data points found that children who grew up with the lowest levels of green space had up to 55% higher risk of developing a psychiatric disorder (Engemann et al. 2019). Studies in biophilic design demonstrate that people living and working in spaces with vegetation compared to those without vegetation show improved performance on mental tasks, more positive moods, greater ability to refocus attention, stress reduction, and diminished perceptions of pain in health-care settings (Kellert et al. 2008).

Additional support for the savanna hypothesis comes from the body of evidence showing that humans often prefer natural environments over built environments (Kaplan and Kaplan 1982). Using data from 30 studies, Kaplan (1992) summarized the results of participant ratings of photographed scenes of Western Australia, Egypt, Korea, British Columbia, and the United States. Across these varied geographic regions, participants preferred natural environments over built environments. Other data suggest that the addition of trees and vegetation increases positive evaluations of built environments, thus demonstrating the transformative power of foliage (Ulrich 1983).

One of the earliest studies to test the idea that people have a generalized bias toward savanna-like environments hypothesized that “innate predispositions” for the savanna should be more likely to be revealed in children than in adults, given that adults have had greater opportunity to experience non-savanna ecosystems (Balling and Falk 1982). In a study that included six age groups (8, 11, 15, 18, 35, and 70 or over), subjects were asked to rate photos from five natural biomes on scales that measured how much they would like to “live in” and “visit” each one. The researchers found that the youngest group (8-year-old children) preferred the savanna over the other habitats on both scales. The deciduous forest, coniferous forest, and savanna were equally liked among ages 15–70, with ratings for the desert and rainforest coming in lower at all ages. The study also implies that people have an aversion to drought conditions and arid landscapes. Photos depicting greener savanna were rated

higher than similar savanna photos taken during the dry season. Finally, all age groups gave the lowest ratings to the desert environment (Balling and Falk 1982).

Causal Mechanisms

Variation in the distribution of landscape preferences can be explained, in part, by three mechanisms (ecological factors, selective migration, and social influence).

Ecological Factors. Features like the prevalence of disease and urban crowding can affect the psychological processes that give rise to preferences. Regional differences in disease prevalence are correlated with several important cross-cultural differences (Murray and Schaller 2010, 2014). According to this view, ecological variation in the prevalence of infectious diseases gives rise to geographic differences in psychological traits. Thus, pathogens are mechanisms that contribute to regional differences in human behavior. Over evolutionary time, the risk of exposure to parasitic diseases has shaped the way humans interact with the physical and social environments. Murray and Schaller (2014) discuss evidence that disease-causing pathogens contribute to geographic variation in sexual behavior, sociosexual attitudes, value systems, conformity, personality, family relations, ethnocentrism, moral judgments, and political ideology.

Several studies have attempted to rate the prevalence of disease-causing pathogens across countries and regions. Gangestad and Buss (1993) used epidemiological atlases to create a single measure indicating the historical prevalence of pathogens in 29 countries. Employing a similar procedure, Murray and Schaller (2014) calculated an index of the historical prevalence of infectious diseases within 230 geopolitical regions around the world.

Selective Migration. People who choose to migrate to a new region or country are often psychologically different from their counterparts who choose to stay behind. There is mounting evidence that individual personality differences are associated with preferences and decisions

about relocating (Jokela 2009, 2014). For example, high openness and low agreeableness personality scores were associated with between-state and within-state migration in the United States, while high extraversion increased within state migration, but not between states.

Social Influence. People who live in different countries, different regions, or even different neighborhoods often follow different customs and norms which, in turn, influence attitudes and behaviors. In Montana, for example, local norms encourage owning a gun and being emotionally reserved, two factors which appear to be partly responsible for the high suicide rate among Montanans (Rentfrow and Jokela 2016).

Conclusion

Research on landscape preferences has focused on how features of the environment (e.g., climate and weather) contribute to the organization of psychological phenomena and human activity. The savanna hypothesis articulates some of the evolutionary forces that helped to shaped human landscape preferences in ancestral environments. In sum, there is a great deal of variation in landscape preferences and at least three causal mechanisms that help to explain this variation. There is still a great deal to learn about the meaningful outcomes of these preferences in the long run (Bennett et al. 2018).

Language Acquisition

Anna Dina L. Joaquin
California State University – Northridge,
Northridge, CA, USA

Synonyms

[First language acquisition](#); [Language development](#); [Primary language acquisition](#)

Definition

Process of acquiring the sound system, structures, rules, and symbolic representations of a language and their meanings.

Introduction

How typically developing children universally acquire their primary language(s) with ease before any or without formal schooling is the foundation of research in language acquisition. There have been two general strands of research: nativist and nonnativist. The nativist approach proposes that an innate module gives humans a priori knowledge about the nature of language, specifically syntax, and results in the universal acquisition of language among all typically developing children (Chomsky 1957, 1975). The second strand assumes that there is no innate mechanism specifically dedicated to language, but innate social and cognitive abilities that have evolved for other purposes. There has been no clear winner as research from other disciplines examining infant and child abilities, parent/adult–child interaction, neurobiology have forced researchers to think and rethink, about whether a language faculty dedicated to language evolved, or have general biological structures and cognitive abilities been exapted for languages to be universally acquired.

What Evolved?

Nativism

Chomsky (1957, 1975) perhaps raised *the* question of language acquisition research. How is it that a child is able to correctly generalize from a finite sample of sentences heard from an unfiltered context the rules of a language, and then apply those rules in such a way that they can correctly produce an infinite number of sentences? In other words, how does one account for the *Poverty of Stimulus*, which necessitates that children acquire and know more about language structure than could possibly be gained from the “noisy” ambient language they are exposed to and with little correction? Chomsky proposed that humans have evolved a species-specific innate capacity, a language faculty, encoded in our biology. This faculty is Universal Grammar (UG) and accounts for the uniformly successful acquisition of grammar of typically developing children despite the Poverty of Stimulus. So, knowledge about one’s language(s) will be triggered through exposure to the ambient language and subsequently produced. As the search for universals among the world’s 7000 languages continued, the arguments made in support of a universal grammar became less and less probable, and the technical theories of syntax have had to change over time (Dabrowski 2016; Horgan 2016). Furthermore, while there has been some promising support for a language faculty, researchers have yet to find a plausible genetic or neurobiological substrate (Lenneberg 1967; Lai et al. 2001).

Behaviorism

Prior to nativism, in his book *Verbal Behavior*, Skinner (1957) suggested that we learn language by making and reinforcing associations through the process of conditioning. In this view, language is learned piecemeal using the same innate mechanisms for learning other behaviors and gaining knowledge. New or previously heard instances of language are generalized and inducted into our existing language repertoires. The behaviorist view was considered insufficient as it was believed that young children experience very little

one-on-one language teaching interactions and much learning occurs without direct instruction. It seemed implausible that children had the ability to cut through the “noise” of the ambient language to make associations and generalizations. However, overtime, research in frequency effects and priming suggests that a Skinnerian view of language acquisition may be more reasonable than previously considered.

Frequency Effects

Frequent exposure to language elements strengthens associations. There is a growing body of research demonstrating that infants are highly sensitive to the frequency of events in their experiences, including the features of a language, and can scaffold the understanding, learning, and usage of the elements of a language with minimal instruction (Hasher and Chromiak 1977; Attneave 1953; Shapiro 1969; Underwood 1971). In fact, frequency effects are ubiquitous in first language acquisition (Ambridge et al. 2015). Chang (2006) synthesized studies showing how frequency effects can account for the acquisition of constructions from the natural environment affect and adjust a learner’s usage overtime due to exposure to different linguistic forms and generalize a word’s syntactic roles and associate it to other words in the same category (Boyland 2001; Bybee and Hopper 2001; Hallan 2001). Effects have been found to occur in children as young as 8-months old who can (1) segment words from fluent speech, (2) store and access information about the sound patterns of words that occur frequently in fluent speech, and 3) retain words even when there is no contextual support from the surrounding environment (Juszyk and Hohne 1997). Two-year-old children can learn word meanings across situations and contexts and get better at this skill as they get older (4 years old) (Akhtar 1999). Though not directly addressed, but with frequency, children are able to learn words simply by overhearing (Oshima-Takane 1988; Oshima-Takane et al. 1996; Oshima-Takane 1999; Akhtar et al. 2001; Akhtar 2005; Floor and Akhtar 2006; Skolnick and Fernald 2003). All things being equal, frequency effects in

children have been observed at the word level (nouns, adjectives, verbs, function words) (Ambridge et al. 2015 p. 244), with higher frequency words learned before infrequent words and are associated with better comprehension and lower rates of error (Schwartz and Terrell 1983). Frequency effects have also been suggested for word strings such as routine four word sequences (i.e., a cup of tea, a cup of milk) in child-directed speech (Bannard and Matthews 2008). However, effects at the level of sentence construction are still unclear.

Priming

While frequency effects are related to the facilitative effects of exposure for making associations, priming refers to the facilitative effects of an encounter with a stimulus on subsequent processing of the same or a related stimulus. The effects may be a change in speed, bias, or accuracy of the processing of a stimulus. Each time we attend to a stimulus (i.e., a picture, a face, a word, phrase), a lasting representation is created that aids in later identification of the same or similar stimulus. Priming can occur as quickly as one encounter, has long lasting effects, and has been applied to language acquisition as well. Church and Fisher (1998) compared long-term auditory priming between English-speaking 2- and 3-year-olds and college students and found that all of the age groups performed similarly. Each participant was more likely to identify words that were heard previously regardless of the obvious discrepancies in previous lexical knowledge. Similar studies showed the same priming effects in preschoolers when stimuli were novel non-English words (i.e., yeeg, lell) (Fisher et al. 2001).

Priming may have a central role in the acquisition of syntactic structure as well, though experiments with young children have been limited. Some studies have used the passive form as the target construction as it is rare in children's spontaneous speech (Huttenlocher et al. 2002). One of the earliest studies with 4–5-year-olds (Whitehurst et al. 1974) indicated that children who heard passive constructions were more likely to produce and comprehend the passive form than children who did not. Syntactic priming effects of

transitive and dative constructions have also been observed (Huttenlocher et al. 2004; Shimpi 2007). Non-lexical priming studies are significant because input to young children is often heard without being repeated. Such studies demonstrate, in experimental conditions, that young children are sensitive to and may be conditioned to syntactic form just through *hearing*, and that form may also be reflected in their subsequent speech.

Social Constructivism

While nativism gained momentum, the influence of pragmatic-based philosophers (Wittgenstein 1953; Astin 1960), emphasizing meaning and the role of language acquisition to achieve social ends, did not disappear. The Vygotskian perspective on language as a cultural tool and the fundamental role of social and interpersonal interaction in development advanced among social constructivists (Vygotsky 1978). Among the more notable, Bruner (1957, 1960) rejected the nativist view and proposed that meaningful language acquisition occurs in the context of parent/adult–child interaction with the support of a Language Acquisition Support System (LASS). His research dramatically shifted the field by videotaping the context of naturally occurring language, as opposed to nativists who examined well-formed idealized sentences to uncover the underlying rules, or Universal grammar, that allow children to generate grammatical sentences. Such research indicated that infants are endowed with far more abilities than previously thought that facilitate communicative development (Gopnik 2009). For social constructivists, what is *a priori* are abilities that can be deployed to achieve social ends, including a disposition to attend to and discriminate the sound system, grammatical constraints, facial expressions, and gestures that communicate and intentions. Bruner highlighted the significance of intersubjectivity, or the ability to share and relate experiences with another. In understanding the intentions and meaning of the other, children also learn to appropriately use language (Bruner 1983).

Social constructivists continued to lay the groundwork for research on the capabilities of neonates and prelinguistic infants, which demonstrates that they are born with abilities to interact

and attune to interlocutors. They also continued to promote the study of adult–child dyads and the role of adults or experts in facilitating social interaction, through which valuable cultural knowledge, including language, is learned.

Discriminating Abilities

Infants have been found to make socially related distinctions and preferences. Hours after birth, infants distinguish between rotten and pleasurable odors (Steiner 1979), and 6-day-olds know the smell of their mother's milk (MacFarlane 1975). The capacity to sense touch begins very early in human ontogeny, as early as a preterm in the third month (Barlow and Mollon 1982; Ellis and Ellingson 1972). With regard to the sense of hearing, studies show that 6-month-olds discriminate features of tempo, rhythm, melody, and key in the structures of both song and instrumental sound (Trehub et al. 1993). Human speech is also salient to a neonate among an array of auditory stimuli in its environment (Cairns and Butterfield 1975; Eisenberg 1975). They have been found to be able to discriminate and show a preference between direct and averted gaze, as well as face-like and nonface-like (Maurer and Barrera 1981; Maurer 1985; Farroni 2002, 2004). They differentiate between human and nonhuman sounds (Eisenberg 1975) and between prosodically different languages (Mehler and Christophe 1995). Moreover, infants are able to decompose the stream of speech in their environment when they are as young as 4-days-old (Bijeljac-Babic et al. 1991; Kuhl 2004; Ramus 2002; Saffran 2001; Saffran et al. 1996; Saffran and Thiessen 2003; Vihman 2014). Thus, humans are born with remarkable abilities to sense and make distinctions of their social world, including linguistic input.

Facial Expressions

Newborns seem to also be born with an inventory of distinctive expressions and vocalizations that can be interpreted as communicative and can lead to interpersonal communication. Facial gestalts resembling facial expressions relating to laughter and crying are observed as early as 32.5 weeks in the womb (Reissland et al. 2011). Facial expressions of interest, joy, disgust, surprise, and distress

have also been observed in young infants (Izard 1978). Trevarthen (1979) argued that the posturing of the head during many forms of facial expression seems to be systematically related to particular facial expressions and suggested that all the patterns of body expression are present in infants at birth, and the gesticulations of infants (i.e., hand-waving, index-finger pointing, and fingertip-clasping movements near the face when they are vocalizing) are clearly not imitations of adult partners. Though not linguistic per se, facial expressions can encourage social interaction with interlocutors, creating spaces to be exposed to linguistic input, and to learn to associate expressions with meaning.

Prelinguistic Gestures

Though it is unclear if the phylogentic or ontogenetic origins of language are vocal or gestural (Hirsh-Pasek and Golinkoff 1996; Karmiloff and Karmiloff-Smith 2001; McNeill 2000; Tomasello 2008) research demonstrates a relationship between prelinguistic vocalizations and gestures, and language development. For example, hand banging is a predictor of the onset of canonical babbling (Bates and Dick 2002). Gesture not only provides a way for children to refer to objects (i.e., pointing), but on average, children gesture an object 3 months before they produce the word for that object (Iverson and Goldin-Meadow 2005). Two-word combinations are also preceded by a gesture-plus-word combination (i.e., point at bird while saying nap; point at bird while saying bird). Others have shown that different types of gestures predict different types of word production (Kuvac-Kraljevic et al. 2013). Beat and iconic gestures appear when utterances become longer than two words (Mayberry and Nicoladis 2000). Therefore, some researchers propose that language and gesture are part of a single integrated system (Goldin-Meadow and Wagner Alibali 2013).

Prelinguistic Vocalizations

Babbling was once considered to simply be a reflection of an infant's motor development and sensitivity to and use of the sounds of their native language. Now prelinguistic vocalizations are considered to be a critical part of *social gating*

and may have a significant role in language acquisition (Jusczyk and Hohne 1997; Kuhl 2007; Oller et al. 2010). The consonants used in babbling (CVCV), for example, are good predictors of the consonants used by infants in their first words (Vihman et al. 1985). Babbling is also a predictor of the appearance of pointing and a child's first words (McGillion et al. 2017).

Prelinguistic vocalizations or utterances are also deployed effectively by infants to achieve various communicative ends including requesting and obtaining food and getting the name of objects, to regulate the behavior of others, to maintain contact with others, to express their feelings, and to play with language (Halliday 1975). Infants also modify their vocalizations to be more speech-like or more mature when they receive feedback from their interlocutors (Warlaumont et al. 2014; Albert et al. 2017). In response, mothers prolong the interactions and increase the use of simplified speech, which often contains information about objects in the infant's social context. Mothers also respond more often when infant vocalizations are directed at objects than those that are undirected.

Infant-Directed Speech (IDS)

Infants also have a clear preference for IDS over adult-directed speech (ADS) (Cooper et al. 1997; Cooper and Aslin 1990; Werker and McLeod 1989; Pegg et al. 1992; Soderstrom 2007). Exaggerated, simplified, and adjusted speech directed at infants has long been assumed to facilitate language learning, as it enhances distinctions between the various aspects of their native language (Kemler Nelson et al. 1989). IDS allows infants to easily identify and categorize vowels and consonants (Cristia 2011; McMurray et al. 2013). Infants have been found to remember and learn words better with IDS when compared to ADS (Singh et al. 2009; Ma et al. 2011). IDS exposure is also directly related to vocabulary growth (Weisleder and Fernald 2013).

Though the characteristics or prosodic features may vary from culture to culture, IDS is a species-typical trait (Ferguson 1978; Bryant and Barrett 2007; Falk 2009). Russian, American, Swedish, Mandarin, Hakka, Japanese, Thai, French,

German, Hebrew, Quiche, Lebanese speaking women use IDS with infants (Pye 1986; Fernald et al. 1989; Kuhl et al. 1997; Kitamura et al. 2002; Fernald and Morikawa 1993; Liu et al. 2003; Farran et al. 2017). Men also modify and heighten the pitch of their speech (Broesch and Bryant 2017; Rondal 1980; Fernald et al. 1989; Gergely et al. 2017). Deaf speakers make modifications as well when they sign to infants (Erting et al. 1990; Masataka 1992; Nonaka 2004).

Though IDS may be species-typical, and "may be phylogenetically widespread and evolutionarily ancient" (See Heyes 2016 for discussion, p. 284), it is not a species-specific trait. IDS is also directed toward nonhumans, and the preference for its characteristics is also exhibited among nonhuman animals (Gergely et al. 2017; McConnell 1991). Thus, some have argued that IDS, and other adult and infant abilities that facilitate learning (i.e., gaze, motionese, imitation, etc.) reflects a *natural pedagogy* or predisposition of experts to *ostensibly manifest* their knowledge to novices to ensure the transmission of cultural knowledge, including language (Csibra and Gergely 2006; Csibra and Gergely 2009). This predisposition was selected for in hominid evolution when tool-making practices emerged and confronted a learner with cognitively opaque behaviors to acquire. Heyes (2016), however, argues that such behaviors were adapted not for teaching or learning, but for the promotion of social bonding or to promote attention to other conspecifics. Regardless, both views hold that such aspects of social interaction are not specifically for language acquisition, though research clearly suggests that they can be facilitative in the process.

Contingency

In addition to IDS, caregivers may use gaze, eye contact, eyebrow raising, and pointing as social cues to index relevant information, which infants recognize as signals that the caregiver has communicative intention (Brugger et al. 2007; Csibra 2010). From birth, we are already participating in and anticipating dialogic practices in multiple ways. When adults use both verbal and deictic communicative signals, they assume that they

refer to the same thing. If there is a discrepancy, for example, in a condition when the pointing does not index anything, infants notice and expect that something should be in the direction of the pointed area (Gliga and Csibra 2009). Trevarthen (1979), who observed that infants move their mouth, hands, and eyes in a turn-taking format with an adult, claimed that humans are born with a foundation for interpersonal communication. Bateson (1979) similarly looked at newborns 49–105 days old and also noticed mothers and infants “in a pattern of more or less alternating, non-overlapping vocalization, the mother speaking brief sentences and the infant responding with coos and murmurs, together producing a brief joint performance similar to conversation” (p. 65). Bateson coined this collaboration *protoconversation*. Jaffe et al. (2001) also showed that 4-month-old infants are highly proficient in vocal turn-taking. If interlocutor’s actions are not contingent to an infant’s behavior or vocalization, infants show sensitivity to the lack of contingency with a loss of positive affect and attention (Murray and Trevarthen 1985).

Thus, decades of social constructivists have shown that human beings are born with a remarkable sensitivity to stimuli in the social world, an ability to discriminate and parse the social input, an inherent expectation and use for communicative signals, and an ability to appreciate the communicative significance of social cues, facial expressions, and gestures, crucial to achieving and maintaining social interactions.

Functionalism

From social pragmatists and social constructivists, a functional or usage-based perspective of language acquisition emerged, one that would also suggest that structure is not innate but emerges from interaction and use. For proponents of this view, what evolved, what is universal is not an innate language faculty, but social cognitive skills, again *not* dedicated to or specifically for language. Tomasello (1999, 2003), for example, focused on two cognitive skills. The first skill is the ability to discern the goals and intentions of their interlocutors through joint attention (Tomasello and Farrar 1986). It involves the

ability to share and follow the attention of other persons, and to actively direct the attention of others by pointing, showing, and using non-linguistic gestures. In doing so, children learn the use and intentions of speakers and formulate scripts and routines of how to use linguistic conventions to achieve social ends. For example, pointing produces joint attentional frameworks with interlocutors, in which infants have been observed to use pointing for declarative, imperative, and interrogative motives (Bates 1979; Carpenter et al. 1998; Begus et al. 2014). The second skill, pattern finding, includes the ability to perform statistically based distributional analyses on various kinds of perceptual and behavioral sequences and to form categories of similar objects and events (Tomasello 2003 citing Gomez and Gerken 1999; Marcus et al. 1999; Rakison and Oakes 2003; Saffran et al. 1996). As children try to comprehend and acquire the language in their social environment to achieve their social goals, intention reading allows them to theorize the function and meaning of an utterance, word, or sentence, while pattern finding gives them the ability to isolate and extract parts of the language they hear and allows them to see commonalities in use and function across different utterances. These two universal sociocognitive abilities allow children to construct the grammar, meaning, and function of the language(s) being used around them to achieve social ends, along with other social abilities mentioned earlier.

Socioemotional Approach

For nonnativists, the picture that emerges, thus far, is that human beings have evolved social and cognitive abilities that facilitate attention to social agents, social bonding, and interaction, creating spaces and social contexts in which cultural learning, including language, can occur (i.e., conditioning, frequency effects, priming, pattern-finding, joint attention, etc.). A socioemotional approach proposes a perspective on language acquisition based on evolutionary biology, neurobiology, and complexity theory. Language is viewed as a cultural artifact that emerges as a complex adaptive system (Prigogine and Stengers 1984; Waldrop 1992). The ubiquity of primary

language acquisition is the product of an innate drive to seek out, attune to, and affiliate with conspecifics – an interactional instinct or a social instinct (Lee et al. 2009; Everett 2012; Joaquin and Schumann 2013; Joaquin 2013). This instinct ensures that the language, formed and shaped through interaction, is passed down to succeeding generations. However, the ontogenesis of language behavior (i.e., its acquisition) does not occur without its evolved biology, which support attentional and motivational processes that entrain children on the behavior of conspecifics, or without its evolved cultural practices for socialization (Rogoff 2003, Rogoff et al. Rogoff et al. 2007; Schieffelin 1990).

Evidence for the instinct is found in neonates' and infants' behavior that manifest an underlying motivation to engage in interactional activity. Infants show agency in the initiation of interactional activity. They are not passive participants or recipients of information in interaction. They actively initiate social engagement through the use of inborn abilities (cooing, vocalizations, gestures, smiling, etc.). For example, infants 3–54-hours-old initiate interaction by deploying a previously imitated gesture (Nagy 2006; Nagy and Molnar 2004). Turn-taking interactions are often initiated by infants who also anticipate the end of their interlocutor's turn resulting in high levels of latched turns (Gratier et al. 2015). Infants can also initiate learning. An infant can choose which object they would like information about by pointing. If pointing is followed by information provided by the adult regarding that object, learning is more likely to occur in contrast to objects that the infant did not point or show interest to (Begus et al. 2014). In interaction, infant utterances are longer in duration and have shorter response latencies if the infant initiated the conversation, in comparison to those initiated by the adult (Ko et al. 2015).

Infants also communicate pleasure and distress when desired interaction occurs or fails. This is observed in still-face studies in which a mother is instructed to display an expressionless, "still-face" in front of their child (Tronick et al. 1979; Brazelton and Cramer 1990). For example, when the child sees his mother, he typically "greet" his

mother with a smile. The mother responds with a still-face and he becomes still and then warily looks away. He then looks toward his mother again and finally he withdraws from the interaction. In another study (Murray and Trevarthen 1985), the infant showed signs of distress, such as grimacing, increased handling of clothes, touching the face, sucking the fingers, and frowning within a few seconds of seeing his mother's "still-face." Efforts to communicate or reinstate interaction were also intensified at first, mouthing and tonguing postures were maintained and accompanied by active gesturing. Eventually, the infant withdrew and averted his gaze downward from the mother's face. Thus, infants take into account the visible emotional stances of their interlocutor and use that understanding to deploy their next action.

Moreover, infants demonstrate a bias for interaction with conspecifics. They make a distinction between human and nonhuman acts and they prefer animate entities to inanimate ones. One and two-month-olds respond to physical objects (i.e., a dangling toy) differently than to a person (Trevarthen 1974). Infants look at, listen to, or touch objects. They also seek and interact with physical objects as sources of interest and as potentially graspable, chewable, and kickable, while human beings are perceived as social and are communicated with through expressive movements that are distinct from those with objects. Similarly, other researchers showed that 2-month-olds smile, vocalize, and alternate their gazes with an adult, but if presented with an object that moves and sounds contingently, infants will engage intense arm activity while staring at the object (Legerstee et al. 1987). Neonatal imitation also may be specific to people, such that inanimate objects that attempt to elicit imitative responses from infants fail (Legerstee 1991).

In addition, infants understand the interactional import of communicative and social cues (e.g., gaze, pitch changes) and more generally are attuned to adults' responses and actions (see Lee et al. 2011; Joaquin 2013 for a review).

Collectively, these behaviors are manifestations of an interactional instinct, and are motivated by biological processes. Endogenous

opiates and neuropeptides (e.g., oxytocin, vasopressin, and dopamine) make interaction with caregivers inherently rewarding and serves as a hardwired motivational mechanism (Depue and Morrone-Strupinsky 2005; Thompson et al. 2004; Popik and Van Ree 1992; Blass and Shah 1994). Neuropeptides are also a part of a system that appraises and marks interactions and the contexts in which they occur as pleasurable or not. Thus, as the child grows, the rewarding aspects of the attachment bond become part of the child's memory, which leads to the approach and development of affiliative bonds with caregivers and ensures cultural learning, socialization, and language acquisition through domain general cognitive abilities (Mates and Joaquin 2013). A similar biology guides the behaviors of caregivers, who through IDS, serve to facilitate and increase affiliation and attachment between the infant and caregiver (Storey et al. 2000; Weismann et al. 2012).

Socialization of language use, or pragmatics, may also be subserved, in part by the prefrontal cortex (PFC), known to be associated with monitoring, learning, and memory of the reward value of reinforcers, and the evaluation of punishers (Schumann 1999; Kringelbach 2005a, 2005b). Therefore, as it is involved in the evaluation of reward, it is important for decision-making (Rolls 1998). Its connections to the amygdala and cingulate cortex also involve the PFC in emotional processing, particularly of face and voice expressions (verbal and nonverbal emotional cues) as it receives inputs from the auditory and visual areas (Baird et al. 2006; Hornak et al. 1996; Mah et al. 2004). Furthermore, it is also linked to an ability to infer the likely thoughts or intentions, beliefs, and desires of others (Heatherington et al. 2006; Kelley et al. 2002). As these brain regions subserve such social and cognitive abilities, they have also evolved to subserve language pragmatics, which a child learns as they are enculturated into society. Indeed, there are many anthropological, sociological, and linguistic accounts of how children are socialized to use language. And, indeed, persons with damage to the PFC or frontotemporal dementia, a neurodegenerative disease affecting the PFC, demonstrate social

and pragmatic anomalies (Brickner 1936; Mates et al. 2010; Joaquin 2010a, 2010b).

Conclusion

Language acquisition is the process in which humans acquire and subsequently produce their primary language(s) for social means. It involves acquiring the sound system, structures, rules, and symbolic representations of a language, and then applying, producing, and combining those aspects to suit one's objectives in social contexts. The issue in language acquisition is: What has evolved for children to come to know so much about language if the input they are exposed to is limited, full of imperfections, and is often not accompanied with correction? There are two evolutionary stories. An economical view proposes that human beings have evolved a language-specific faculty in our biology, which accounts for the ubiquity of language acquisition by all typically developing children. However, since its proposal, the language module has not been biologically substantiated and it is still up for debate. What has been substantiated is a vast array of domain general abilities that behaviorist, social constructivist, functionalist, and socioemotional researchers have suggested are significant for cultural learning and language acquisition. Discriminating abilities, prelinguistic behaviors, frequency effects, priming, pattern finding, and joint attention combined with infant-directed speech and socialization practices, and a biologically driven motivation to attune to, affiliate, and bond with conspecifics make language input more accessible than previously thought. Any explanation of language acquisition must also consider these evolved abilities, processes, and biological structures.

Language Acquisition in Infants and Toddlers

Chelsea Loeffler
Oakland University, Rochester, MI, USA

Synonyms

Language development; Learning; Verbal achievement

Definition

How children approach the complex learning of language and speech development.

Introduction

Since birth, it is clear that eye contact is one of the main nonverbal forms of communication for a child and adult, but in these stages, the child begins to acquire the form of language. Language is part of what makes us human since humans are the only mammals to communicate with verbal languages of our own. Language can be best described as a symbolism of thought which allows us to vocalize what we are thinking and feeling. Children all learn at different rates, but much research has shown that the best acquisition comes from gradual interactions between other people and the environment.

Language Acquisition Milestones

Throughout the learning of language, parents/caregivers are their child's best tool for learning, and the way the adult interacts with the child will determine the path of language development they take. From birth to 3 months, the child's main form of communication is crying, whimpering, or screaming. Around 4–6 months of age, infants will have what sounds like their own form of language, such as babbling. Even though we most likely will not understand it, this is a crucial milestone as this is when an infant is learning the rules of language, by moving their lips, teeth, and tongue, they are learning that they can make sounds; it is like a game for them to play. From 7 to 12 months of age, infants make sounds as if they are making sense because they are trying out patterns of sounds in an order similar to mirroring their caregiver which is why reading to children at night is so encouraged. From 13 to 18 months, the infant at this stage will typically be saying one or two words, and what's even more significant is that they will recognize what those words mean (Golinkoff et al. 2015). Around 19 to 24 months, the infant understands much more words than they can speak yet they are learning new words every

single day and start putting short phrases together such as "Carry me." Although some children may take longer to pick up on words, this is simply a guideline for language development.

How Do Infants Learn Language?

Words said by parents/caregivers provide infants with minute artificial languages that embody specific aspects of our natural language arrangement. Once an infant has become accustomed to the sample of this language, a new sample, or a sample from a different language (if bilingual family), is presented to the infant, such as a new word or phrases. Subtle measures of surprise (e.g., the length of time when looking toward the new sounds that were made) are then used to assess whether the infant has learned the new word to be the same or something different. In this strategy, we can ask what the infant learned from the sample language (Christiansen et al. 2016). These repeated patterns are the learning mechanisms underlying the earliest stages of language acquisition for infants.

Language Acquisition and Language Evolution

In 2009, Chater and Christiansen posed an interesting discussion from an evolutionary perspective which highlights on the idea that when it comes to learning language, the child faces a problem of training. For an infant, the objective is to coordinate with others such as the parent or caregiver rather than to model the structure of the natural world. They argue that modeling from the parent is dramatically easier, yet then one is left to question when culture plays a role and how that cultural form arose through processes of cultural revolution. When the child aims to learn an aspect of human culture (rather than an aspect of the natural world), learning language is dramatically simplified – because culture (including language) is the product of past learning from previous generations almost like following in your parents' and grandparents' footsteps since most linguistic researchers will agree that overall language is very stable over the course of the years.

Conclusion

This discussion has aimed to demonstrate that when it comes to language acquisition for infants and toddlers, it is not something that happens without effort nor quickly; it is a gradual progression. Many processes and systems are constantly working together to create a logical pathway for children to learn how to speak that even though we think of it as second nature, it is a complex puzzle which is constantly developing throughout our lives.

Definition

The process of children acquiring the knowledge and skills of comprehending and using language that takes place in the home context.

Introduction

The past 20 years of language and literacy research has made significant advancement in our understanding of the ways in which children acquire language and literacy skills in the home milieu. Children's early oral and written language knowledge and skills are seen as emergent and continuously developing with increasing importance being attributed to family literacy environments and the role of parental engagement and investment. This entry aims to map out the pathways in which children's language and literacy acquisition is ushered through interaction with various home-based elements.

A Developmental Perspective on Child Language and Literacy Acquisition at Home

The term “emergent literacy” refers to the precursors of formal reading, such as young children's concepts of print, awareness of sound-letter correlation, letter and word recognition, and writing, knowledge of functions of written language. This term, coined by Teale and Sulzby (1986), marked a significant turn of understanding child's language development and education from readiness-based to an experience-oriented perspective. From the early till mid-twentieth century, major work in child development theories and applications in education was dominated by a “maturationalist” perspective, deeming it appropriate for a child to wait until he/she intrinsically progresses to readiness in cognitive and motor skills to begin formal literacy instruction. To distinguish from the “reading readiness” approach, Teale and Sulzby (1986) argued in their foundational work, *Emergent Literacy: Writing and Reading*, that young children's literacy begins

to emerge and develop at very early age, long before what has been conventionally prescribed. More importantly, this perspective of early literacy acquisition recognizes the importance to literacy learning through learners' exposure to and engagement with print and reading and writing practices in real-life settings, especially their home environments.

In the first several years of a child's life, family tends to be a child's primary source of linguistic input. Young learners' exposure to oral and written language in the home context is crucial to their language acquisition in the initial stage. Parents interact orally with their children regularly and systematically throughout their developmental age span. Parents' vocabulary skills have been proven to be a key contributor to the quality of linguistic input that children receive. This holds true not only for monolingual families – Lewis et al.' (2016) study of Spanish-English bilingual children concluded that children's vocabulary skills in English (L2) is especially sensitive to the fluctuations in primary caregivers' language use (although children's early exposure to native language has been proven not detrimental to their second language acquisition). In addition, children's oral exchange with parents also plays a decisive role in cultivating their perception and comprehension of speech, and communicative competence.

The availability of paper-based and digital-mediated print materials is a key constituent of physical literacy environment at home. Children can acquire many things through interacting with books. Once children embark on an exploratory journey into books, they begin to construct fundamental rules of prints. Even young children engaging in pretend reading activities demonstrate their established concepts such as books are for reading, and static pictures are representations of things and events.

It is worth noting that the proliferation of modern technology has dramatically increased young children's access to digital media devices (e.g., iPads) at home in addition to traditional screen activities (e.g., TV, DVD). Although the appropriateness of digital tools in young children's lives has been fervently debated mainly out of concerns

with children's physical and social development in early years, research suggests that children inevitably become socialized into digital practices through their observations of and interaction with adults and peers who use digital tools. Even parents taking precautions to limit best they could their children's access to electronic media view digital tools as a source of positive learning experience for their children (Teichert 2017). Despite the fact that little existing research explored relationship between literacy outcomes and children's engagement in digital-mediated literacy activities, the new interactive model (e.g., long-distance communication, joint participation) and affordance of multiple modes of texts (aural, visual, linguistic, textual, etc.), which are characteristic of digital media, potentially affect young children's literacy development and outcomes.

Factors Affecting Home Language Acquisition Environment and Outcome

A rich body of qualitative studies have corroborated remarkable predictability of family biographical characteristics (e.g., socioeconomic status/SES, ethnicity, gender) and children's early literacy achievement and later academic development. The relationship between SES and monolingual children's vocabulary development has been robustly demonstrated in many studies; ethnicity has also been indicated to play a role in shaping children's initial reading readiness and later growth. Recent attention has been particularly paid to the correlations of SES with bilingual children's language and literacy competence. For example, Buac et al. (2014) reported that SES was among the factors that strongly predicted Spanish-English bilingual children's English vocabulary skills.

The quantitative strand of research complements the descriptive studies that reveal the ways in which different family variables shape qualitatively different language acquisition experiences at home. James Samuel Coleman's (1988) social theory of family capital maintains that the family as a dynamic entity actively transforms various forms of capital from the parent

generation into the educational attainment of their children. In general, Coleman distinguishes three major forms of capital in the family environment: physical or financial capital (material resources measured by family income and wealth), human capital (individual's level of educational attainment embodied in a person's knowledge, skills, and capabilities to act in certain social structures), and social capital (social resources embedded in the network of social relationships both within and between family and community).

Family capitals are indexical of various components of home environment. The affordance of both traditional paper-based and modern digitalized prints is often symbolic of family physical capital; the educational level and (bilingual) literacy proficiency of parents or primary caregivers and the quality and frequency of them involving in joint literacy activities with children are captured by human capitals. Finally, family social capital signifies the importance of extended family ties and community social and linguistic resources as important contributors to children's language and literacy abilities. Home environments, when properly and actively capitalized, can be transferred to young learners' positive oral and written language outcomes. Therefore, family capital theory serves as a useful tool to unpack the assorted elements that reflect the quality of a child's home environment, and how the intricate embroidery of home environment synchronizes children's early language and literacy development with the contemporary social and technological advancement.

Although family capitals reflect the quality of a child's home environment, not all family capitals are equally transferrable to children's literacy outcomes. Rather, it is the way the family utilizes its existing capitals and invests them in children's learning process that acts a central role. In a major study, Li (2007) explored in depth the home environment of four Chinese immigrant families in Canada (two academic families and two entrepreneurial families). She ascribed academic families' success in cultivating children's English learning to parents' ability to make more educated choices (derived from parents' human

capital), including investing their limited financial capital in materials beneficial to children's learning and building social networks in the English-speaking communities (social capital). Parents from the two entrepreneurial families, despite of their better-off financial conditions, were incapable of mobilizing various forms of family capitals to meeting their children's immediate language needs. Thus, the accumulation of family physical/financial capital is not the determinant of the quality of family learning environments; Li concluded parental human capital is central for the families to transfer other forms of family capital into their children's language learning.

The Role of Parental Involvement in Language Acquisition at Home

While literacy is an amalgam of cognitive and linguistic skills, transferable from one context to another, it is also a social practice (Li 2001; Street 1995). This social practice perspective recognizes literacy as culturally situated and socially coconstructed; and it varies from context to context. Thus, everything a child learns about literacy is shaped by their experience about its functions and values demonstrated by the competent members at home.

Early literacy acquisition recognizes social support systems of learning, especially the role of scaffolding, direct instruction, and modeling that parents provide to facilitate children's participating in home-based reading and writing activities. Yet, specific associations exist between different types of home literacy activities and the development of specific emergent literacy skills. Sénéchal and LeFevre (2002) identified both informal and formal literacy experiences that children are exposed to at home. Informal literacy activities (e.g., parent-child shared book-reading) focus on the message contained in the print rather than the print per se.

Parent-child joint book-reading has been extensively researched as a prototype of white, middle-class home literacy practices. Parental scaffolding (e.g., parents expanding on the

meaning of the story, answering children's questions relating to language/story) creates a developmentally sensitive context with potentially rich source of information and opportunities for children to develop language knowledge and skills. Despite of the consented benefit of parent-child shared reading in children's emergent literacy development, storybook exposure has only been found to contribute to oral language skills (i.e., receptive vocabulary, listening comprehension, and phonological awareness). Rather, it is parent involvement in teaching children about reading and writing knowledge that indicates a more positive relationship with the development of written language skills. Formal instruction draws children's attention particularly to the structural features of the prints, reinforcing knowledge regarding the concepts of prints, alphabetical knowledge, word spelling, etc.

The literacy as social practice approach also validates a wide array of ways in which literacy is taught and learned among low SES and language minority families that fall outside the mainstream purview. While parent-child shared book-reading with young children is an iconic literacy practice in mainstream families, it is foreign to many cultures that value oral storytelling and other forms of literacies (Mui and Anderson 2008). Young children from nonmainstream families may develop literacy through engagement in home-based religious practices, structured play, and use of texts with functional purposes (recipes, notes, etc.) (Li 2001). In many of these families, in addition to parents, other members such as siblings may assume parents' role in home literacy activities. In her study with Bangladesh-origin families in London, Gregory (2001) presented the synergistic model among siblings where older children assume the teaching role to present information to the younger children in various ways while likely enhancing and reinforcing their own literacy in the same time. Existing research also identified the bidirectional flow of literacy knowledge where language minority children play the expert role to assist their parents with second language comprehension and use. This sociocultural approach to emergent literacy maintains that children from

nonmainstream homes, despite of their relatively low reading and writing achievement records in schools, are "*learners and do learn* about the ways in which written language functions to the degree to which they experience it" at home (Purcell-gates 1996, p. 427, italics in original text).

Finally, parents' modeling of literacy activities, although without directly engaging children in the use of reading or writing, facilitates children's acquisition of literacy knowledge by demonstrating the use of written language in different domains of family life. Children continuously gain implicit understanding of the social functions of literacy while observing their caregivers reading books and magazines, using dictionaries, jotting down shopping list, composing and sending emails or text messages, watching Youtube videos and playing video games, etc. Putting altogether, literacy as social practice reveals how forms of family capital are mediated into children's literacy development through active engaging and coconstructing written language knowledge with children in real-life settings across culturally and linguistically diverse households.

Conclusion

Language acquisition at home offers a distinctive perspective of children's language development outside formal instructional settings such as classrooms. The emergence of young children's oral and written language knowledge and abilities at home is a sociocultural process closely woven into the tapestry of physical and social home environment. The existing work in language and literacy research and education has jointly painted the mural in myriad ways in which children acquire language(s) across linguistically and culturally diverse home milieus.

Language Acquisition Outside the Home

Geoffrey Sockett
Université Paris Descartes, Paris, France

Synonyms

[Language development in formal and informal educational contexts](#)

Definition

Processes by which first and/or additional languages are developed through interaction with language users and resources beyond the immediate family.

Introduction

First language acquisition studies typically observe parent-child interactions longitudinally in order to identify patterns of language development. Studies of language acquisition outside the home may focus on the role of formal education or of social interaction with peers either in face-to-face contexts or increasingly in online environments.

Views of Acquisition

In the second half of the last century, the two broad views of language acquisition, whether the acquisition of a first language or that of an additional language, were an innatist perspective, typified by the work of Chomsky (1957) and a socio-constructivist perspective, building on the work of Bruner (1983) and others. While initially presented as competing models, it is possible to consider a measure of compatibility between these two perspectives, since some basic innate cognitive skills are required to explore and develop language while an absence of social interaction inhibits the acquisition of language. However, the uniqueness of these cognitive functions (Chomsky's Language Acquisition Device) to the development of language is now challenged by many researchers.

In the twenty-first century, work on the acquisition of communicative skills and the development of grammar, by researchers such as Tomasello (2003), Ellis (2002), and Goldberg (1995) among many others, has contributed to a view which links language skills closely to social interaction. Larsen-Freeman and Cameron (2008) present general cognitive functions such as establishing joint attention, understanding the communicative intentions of others, forming

categories, detecting patterns, imitating, noticing novelty, and having the social drive to interact with others as key to the development of first or additional language skills.

Current Fields of Research

In the past, the study of language acquisition outside the home has often been limited to the influence of formal and informal learning in schools, whether through interactions with the teacher or from friends in the playground. The performance of young learners has often been a focus of such research since the plasticity of young vocal chords and the absence of an entrenched first language, among other factors, contribute to young migrant learners, for example, quickly outstripping their parents in second language acquisition through such interactions.

Research into language acquisition outside the home in the twenty-first century tends to focus on the affordances of the Internet in the development of social networks which bring language learners into contact with proficient speakers of the target language. Extensive exposure to online video, social networking, interaction in massively multiplayer online role-playing games and even simply music with target language lyrics has been shown to significantly influence the development of second language skills in particular (Sockett, 2014).

The notion of language identity is key to understanding why learners do not simply reproduce their parents' patterns of language use when learning in a new context. Language is essentially a means by which to represent oneself to others. Researchers such as Norton (1997), Rindal (2010), and Cole and Vanderplank (2016) have shown that subconscious imitation of linguistic conventions used by a social group viewed as desirable by the learner leads to measurable differences in language production. Typically learners focused on formal classroom teaching will adopt the accent and grammatical conventions of that context, whereas learners engaged in informal activities and interactions with target language peer groups will similarly reflect the accents and conventions of those groups.

Conclusion

Future research into language acquisition outside the home will necessarily focus on mobile learning phenomena which have continued to develop in the second decade of the twenty-first century. Since the Internet is increasingly accessed via smartphones which themselves use data about the movement and location of the user to provide services, language acquisition research will increasingly need to study learners holistically as they work, play, and seek to construct plural language identities in interaction with complex networks of other language users around them.

Definition

Language and linguistic features have long been speculated to affect various aspects of human behavior. Being intricately linked with cultural systems, linguistic features can encode and make salient specific cultural values, which are then reflected in behavior. Here we talk about two significant linguistic features, pronouns and terms of address, which are hypothesized to have an influence on cooperative behavior. Such effects are said to be mediated by the encoding of social hierarchical structures and contextualization (or decontextualization) of speaker and addressee in speech.

Introduction

The economic literature contains repeated claims that linguistic features such as tense and pronouns influence economic behavior (Weber and Mavisakalyan 2017). This idea comes all the way back from Edward Sapir and Benjamin Lee Whorf who claimed that the particular language one speaks *determines* the way one thinks about reality (Hoijer 1954). Much of

these effects are mediated by cultural constructs which linguistic features symbolize. If economic theory and experimental economics can have a clarifying role with respect to this Whorfian theory (hereafter referred to as the Linguistic Relativity Hypothesis), it is by modeling and probing the plausible mechanisms through which this influence from language and culture is likely to be mediated to behavior.

Language has been implicated as affecting a wide variety of behaviors in humans like patience, future-discounting, and policy support (Chen 2013; Pérez and Tavits 2017); gender roles in household and educational attainment (Davis and Reynolds 2018); hierarchical and social roles (Weber and Mavisakalyan 2017); and individualistic and collectivistic sense of identities (Kashima and Kashima 1998). Linguistic features such as pronominal structures and terms of address also encode information about joint action, coordination, and cooperation. The latter will be the main issue tackled in this entry, following a brief overview of the nature of linguistic relativity and the way it has penetrated thinking about economic behavior.

Linguistic Relativity Hypothesis

The *Linguistic Relativity Hypothesis (LRH)* puts forward a combination of a linguistic and a psychological claim: (a) languages differ in various ways, including structure, syntax, usage (linguistic claim); (b) these differences influence our thinking, behavior, and decision making (psychological claim). In other words, differences in linguistic structures and usage may have a systematic influence on cognition and behavior of their speakers. LRH has been put forward in both general and specific, as well as strong from weak versions (Scholz 2016).

In the general version of LRH, no certain aspect of cognition is pointed out, and it is said that some linguistic features systematically influence certain aspects of thought, whereas in the specific version of LRH, particular linguistic features are said to have an effect on specific cognitive features. In the present discussion, the

specific version of LRH is brought out by pointing out linguistic features that can directly affect cooperative behavior, and an outline of the specific cognitive and cultural features which lead to this. Therefore by validating the specific claims of LRH, the general version automatically gets substantiated. Strong and weak interpretations of the LRH, on the other hand, discuss the *extent* to which language can determine cognition. While the strong version professes that language determines thought and behavior, weak (or moderate) versions propose an influence of language in systematic ways. Here, we deal with the latter by showing various influences of linguistic features via different cultural constructs.

Language, Culture, and Cognition

Language represents the symbolic environment of a culture. In a complex web of interactions, language and culture can affect each other in various ways. While language is the major medium through which culture is transmitted, allowing it to be a formative element, it is also a product of various cultural traditions, reflective of cultures and their characteristics (Fig. 1). By being the major mediating element, language can not only shape the content of cultural beliefs, but also lead to preservation, amplification, and diffusion of various attitudes, norms, and values. These, in turn, can have major effects on social behavioral patterns, such as cooperation. For instance, it has been proposed that languages, which grammatically associate the future and

the present, tend to foster more future-oriented behaviors like higher savings, prudent retirement plans, lesser smoking, taking better care of health, etc. (Chen 2013).

Simultaneously, various practices, norms, and structural features of cultures are often reflected in the languages that their people speak. An example is the differences between verbal insults in individualistic and collectivistic cultures. In individualistic cultures, where there is a high focus on the individual and a greater sense of self agency, insults are heavily directed to the individual only. However, in collectivistic cultures, which give high importance to interpersonal relationships, verbal insults are predominantly directed toward one’s significant others along with the individual himself (Semin and Rubini 1990). Therefore, when culture is the issue, language is a major mechanism through which the influence is channeled toward behavior, in turn, bringing us in the presence of a Whorfian hypothesis.

In particular, linguistic features can influence hierarchical structures and interpersonal relations in society. A major cultural dimension that has been linked to language is that of individualism and collectivism. Individualistic cultures are those which have a focus on the individual, characterized by values of high independence of the individual, self-reliance, and a struggle to stand out of the crowd. On the other hand, collectivistic cultures place a larger focus on the social context of the individual by emphasizing interdependent relationships and harmony in the idea of togetherness. Individualism and collectivism

Language and Economic Cooperation, Fig. 1 The web of interactions between language and culture, leading to influences on individual cognition and behavior, in the moderate version of the LRH. (Adapted from Weber and Mavisakalyan 2017)

have been directly linked with cooperative behavior, and distinct patterns of cooperative behavior have been noted in the two different cultural constructs (Wagner 1995; Chen et al. 1998). Moreover, distinct arrangements of interpersonal relationships also have a direct effect on cooperative behavior as was famously shown by a large-scale cross-cultural study by Henrich et al. (2005). Here, we talk about the two specific linguistic features which have been shown to correlate with individualism-collectivism and structures of interpersonal relationships, alongside discussing the implications for cooperation.

Linguistic Features and Cooperation

Terms of Address

A term of address is an expression commonly used to designate the person one is talking to. Languages can widely differ in terms of addresses that they employ and in the ways their speakers are required to use them in conversation. For instance, in Korean, in many contexts, one has to use a term indicating one's "hierarchical" position with respect to the addressee: "eomonim" (mother), "seonsaengnim" (teacher), or "seonbae" (to address a senior). The use of such terms of address, signal deference and make the social distance between interlocutors more salient. This, in turn, leads to a perception of fairness and reciprocity in hierarchies, affecting cooperation (De Cremer and Tyler 2007).

Moreover, the rigidity of such systems can signify the *strength* of the social hierarchies. The use of terms of address in Korean is much more rigid than that in English, leading us to predict that the cultures will reflect a stronger hierarchy, hence have a stronger effect. In English, similar terms exist, but speakers are much less constrained to use them. Inspired by a claim of Kashima and Kashima (1998), it can be hypothesized that the existence of a more hierarchical system of terms of address reflects a higher tolerance to inequality in social roles. Therefore, by affecting interpersonal relationships, these linguistic features can induce various

hierarchical social structures, affect inequality tolerance, and further affect cooperation between people.

Pronouns

Pronouns are primary linguistic features which specify the role of both speaker and addressee, along with placing them in a social context. Kashima and Kashima (1998) have stressed upon the importance of these linguistic features to determine key dimensions of culture, such as individualism versus collectivism and egalitarianism versus hierarchy, in view of economic outcomes. The case of pronoun usage can be further formulated into two further questions: (a) *which* pronoun is to be used; (b) *whether* to use a pronoun or not.

Personal Pronouns

Personal pronouns identify not only the addressee, but also index the speaker in a specific type of social context and relations. In addressing the first question of pronoun usage, both first- and second-person pronouns can have distinct forms in different languages, for instance, those linked with politeness distinctions (Helmbrecht 2005). The existence of these distinct forms affects inequality tolerance and cognitive saliency, which can have implications for cultural norms associated with hierarchy and egalitarianism (Weber and Mavisakalyan 2017). Moreover, by affecting inequality tolerance and cognitive saliency, there are expected effects on cooperative behavior.

There have been seen to be varying degrees of politeness distinctions in second-person pronouns in different languages. While languages like English use only a single term for all (you), others like German and Spanish have two different singular second-person pronouns (e.g., *du*, *Sie*; *tu*, *usted*), whereas Hindi and Bengali have three distinct pronouns (e.g., *Tu*, *tum*, *aap*; *Tui*, *tumi*, *apni*). These are used to designate social distance in interactions. According to Kashima and Kashima (1998), speakers of languages with multiple you's are more conscious of status or social distances than the speakers of other languages, leading to a difference in hierarchies in

interpersonal relations. Such social structuring can be linked to cultural dimensions of individualism-collectivism, conservatism, power distance, etc., reflecting on social behavior.

Some languages also have distinct forms of first-person pronouns, for instance, Japanese. Japanese utilizes multiple forms of “I,” like *watashi*, *boku*, *ore*, depicting the speaker in varying social roles and positions. In such cultural settings, one’s social roles are an important determinant of responsibility in social situations, going back to the idea of collectivism. Conversely, languages with a single first-person pronoun signify the individual as the locus of moral and social responsibility (Kashima and Kashima 1998). This reflects high egalitarianism, making the individual autonomy salient.

Pronoun Drop

Pronominal drop (hereafter referred to as DROP), referring to the second question of pronoun use, is a linguistic phenomenon, in which the pronouns can be omitted in their position of grammatical subject of a sentence, without losing meaning of the utterance. In Spanish one can say, “I am eating” in both the following ways: ‘*Yo estoy comiendo*’ and simply ‘*Estoy comiendo*’. In the second sentence, the pronoun ‘*Yo*’ has been dropped. A DROP language may have the effect of reducing the psychological prominence of the actor (both for the speaker herself and the addressee) and symbolically embed the actor in the context, propagating the collectivist worldview. Contextualization is an important effect of pronoun drop (Weber and Mavisakalyan 2017) that takes place by modulating effects on cognitive saliency and can further affect cooperation (Markus and Kitayama 1991). This can be seen in the examples of South Asian languages, like Hindi, where one can utter the equivalents of both “I ate the cake” and “ate the cake” (without the pronoun).

Conversely, languages necessitating the use of subject pronouns to retain the meaning of the utterance, affords a symbolic prominence of the individual actor in everyday conversation and context, for example, in English. This may

strengthen the psychological effect of affluence, pushing people further in the direction of the individualist worldview. In particular, the mandatory usage (or omission in DROP languages) of the first-person pronoun has been linked to the construction of a social situation, where the speaker is differentiated from the context of speech, which includes the conversation partner. Further, pronoun drop is an emphasizing tool for “autonomy” versus “embeddedness” in cultures, which has important implications for economic, social, and political behaviors (Licht et al. 2007).

The World Atlas of Language Structure Online (WALS Online; Dryer and Haspelmath 2011) identifies many languages that allow dropping of the pronominal subject, most notably in regions of East Asia, Southeast Asia, and South Asia, as well as the Spanish and Portuguese spoken in Latin and Central America, many of which have also been known to have collectivistic cultures.

Further Research for LRH and Cooperation

Any serious discussion on the role of linguistic relativity requires the answering of three questions: (a) Which aspects of language influence which aspects of thought in some systematic way? (b) What form does that influence take? (c) How strong is that influence? A thorough investigation of the first question is the most important step that can lead to answering the following two. Here, we suggest an experimental setup for the particular case of a systematic influence of language on economic cooperation.

A powerful way for validating the LRH for language and economic cooperation is running cooperation experiments on bilingual individuals. By priming bilinguals to one of their spoken languages (with differing linguistic features), the effects of those linguistic features on cooperation can be studied. This methodology was successfully utilized by Pérez and Tavits (2017) to demonstrate the effects of future tense of a language on future time perception and thoughts on

politics. In the case of Estonian – Russian bilinguals (Estonian being a futureless tongue and Russian being a futured tongue), when primed to Estonian, effects of future discounting were observed (hypothesis: a futureless tongue conflates the present and future, making the future seem closer to the present) and on being primed to Russian, the effects of future discounting disappeared (hypothesis: futured tongue use different words for the present and future, making the future seem distinct and distant). Such cases of sampling bilinguals from the same population can be particularly noteworthy, as the influence of language can be directly observed, removing other cultural confounds. Though such experiments have not yet been carried out in the specific realm of cooperative behavior and economic cooperation, given the influence of language on above mentioned social constructs, effects can be expected.

Conclusion

Cross-cultural psychology has been relatively silent about the role of language in culture, but the idea of linguistic relativity is steadily becoming more popular. If language can be regarded as providing symbolic tools with which people construct their symbolic world to render their material environment meaningful, this symbolic tool might have the potential to modify the way in which the material world is understood. Here we discuss such modifying effects of language on social behavior, by implicating various cultural and social constructs. Linguistic features, specifically those that signify hierarchies and contextualize (or decontextualize) interlocutors, can affect economic cooperation in meaningful ways. This can have important implications for areas of psychology and behavioral economics, where task framing can significantly alter behavioral outcomes. It, therefore, becomes important to understand linguistic influences, not only for experimental purposes, but also for a deeper understanding of how the cultural mind works.

Language and Handedness

Michael Corballis

Psychology, University of Auckland, Auckland, New Zealand

Synonyms

[Dominant hemisphere](#); [Major hemisphere](#)

Definitions

Hemisphere of the brain considered to play the leading role in hand preference and skill, and in mental processes such as language. The opposite hemisphere is sometimes described as nondominant or minor.

Mirror system: A network in the primate brain that responds to both the production and the perception of voluntary manual actions.

Introduction

Interest in the relation between language and handedness dates from the discovery by Paul Broca in the 19th century that the left hemisphere of the brain was primarily responsible for articulate speech (Broca 1861). Since most people were right-handed, implying left-hemispheric control, the left hemisphere was generally referred to as the dominant or major hemisphere, with the right hemisphere relegated to subordinate status as non-dominant or minor. It was also assumed that dominance was reversed in left-handers, so that speech would be controlled by the right hemisphere. For a time this was known as “Broca’s rule,” but it soon emerged that it did not always hold. As early as

1868, Hughlings Jackson remarked on the case of a natural right-handed man who suffered from expressive aphasia along with left hemiplegia, suggesting that speech was represented in the right hemisphere. Such cases of so-called *crossed aphasia* have since been frequently reported; in their classic monograph, Penfield and Roberts (1959) cited reports of 53 cases of right-handers with aphasia following right-hemispheric lesions, and 63 cases of left-handers, or “predominantly left-handers,” with aphasia following left-hemispheric lesions.

More recently still, it has emerged that the majority of left-handers are actually left-dominant for language. This first became evident from studies of the effects of the sodium amytal test, administered before surgery to determine the hemisphere dominant for language prior to surgery. One large-scale study of 122 left- and mixed-handers showed that 70 % were left-dominant for language, with 15 % showing bilateral representation and only 15 % with right-hemispheric dominant (Milner 1975). Similar figures emerged from studies of the effects of unilateral electroconvulsive therapy. These studies were based on clinical samples, but neuroimaging assessments of cerebral asymmetry for language in nonclinical samples confirm that the incidence of left-hemisphere language dominance is typically in the range 70–80 % (see Badzakova-Trajkov et al. 2010 for evidence and review). This percentage is still lower than that reported in right-handers, which ranges from 95 % to 95 %.

Genetic Models

These findings have been incorporated into models in which handedness is not so much a question of left- versus right-handedness as one of degrees of right-handedness. Left-handers are then considered part of a subgroup lacking a so-called “right-shift” factor, perhaps of genetic origin, where handedness is a matter of chance (Annett 2002). This subgroup, then, is divided between left- and right-handedness, with some displaying ambidexterity rather than consistent

handedness. In genetic versions of this model, homozygotes for absence of a right-shift (or dextral) gene are equally divided between left- and right-handers, homozygotes are all right-handed, while heterozygotes fall in between. Such a model can reasonably account for the relations between handedness and cerebral asymmetry for language, on the assumption that the same gene underlies both. In the case of left-handers, then, it cannot be assumed that cerebral asymmetry is reversed; it is more likely that, relative to right-handers, they show a lower incidence, and perhaps degree, of left-cerebral dominance.

Multiple Genes, Multiple Circuits

Although this approach has proven reasonably successful, there are complications. There has been little success in actually locating the putative right-shift gene, and the evidence now suggests that there are probably several genes underlying handedness, perhaps as many as 40, with each operating to influence the presence or absence of a disposition to right-handedness (McManus et al. 2013). Cerebral dominance itself appears not to be unitary. In one study, indices of cerebral asymmetry were computed across different brain regions in a large sample of individuals in a resting state, and factor analysis of these indices produced four factors, implying four independent lateralized networks, two biased to the left hemisphere and two to the right (Liu et al. 2009). Only one of these was the left-lateralized language network. Using a similar approach, another study of activity in regions of the frontal, temporal, and parietal lobes while participants undertook language tasks and observed manual gestures produced three left-lateralized factors, one representing language and two representing manual gesture (Häberling et al. *in press*). Handedness was only weakly associated with the language network, but was relatively strongly correlated with one (but not the other) gestural network. This network was located in the parietal lobe.

Research is therefore uncovering increasing complexity in the lateralization of networks in

the brain, with different left-lateralized networks for language, manual skill, and handedness itself, and probably different right-lateralized networks for nonverbal components such as face recognition, music perception, and spatiovisual processing. In each case it seems likely that lateralization is a matter of degree rather than a dichotomy, and that there is no systematic reversal. As in the case of handedness, reversal is a matter of chance when a congenital bias is weak or absent.

Evolutionary Aspects

From a more evolutionary perspective, brain development seems to reflect a trade-off between bilateral symmetry and asymmetry. Bilateral symmetry is a natural adaptation in organisms that move, but in which there are no systematic environmental biases from one or other side. So it is that sensory organs and limbs are bilaterally placed, shaping a largely bilateral brain. But with increasing pressure for more complex cognition and increase in brain size, and the demand for multiple specialized circuits, bilateral symmetry would tend to give way to lateralization, with a lessening of duplication and wasted neural space. Lateralized processing is evident in great apes, who show population-level right handedness, albeit at a lower incidence than in humans, and asymmetries in areas homologous to language areas in humans (Hopkins and Nir 2010). In bipedal hominins, these trends increased, with the advent of tool technologies, advanced social cognition, and eventually language. Brain circuits grew more specialized, resulting in what has been termed “hierarchical specialization,” with specialized networks arising from common ancestral ones. New circuits are formed through fissioning of ancestral systems, copying and differential modification of existing circuits, or sometimes through modified circuits fusing to create new functions (Oakley and Rivera 2008). It may well be the case that specialized networks for tool use, gesture, and language fissioned from the “mirror system,” a network in the primate brain dedicated to the production and understanding of intentional

manual acts. Such processes are of course more compatible with evolution through natural selection rather through the creation of new networks, and suggest that language itself evolved from intentional movements of the hands.

Conclusion

The idea that one hemisphere of the brain, usually the left, is dominant for manual action and language no longer holds. Handedness is only weakly correlated with cerebral asymmetry for language, and it is emerging that there are a number of lateralized networks in the human brain, and that handedness is part of a different network from that mediating language. In evolutionary terms, though, networks for language, gesture, and manual operations such as tool use may have emerged from the primate “mirror system,” initially specialized for manual grasping, which became increasingly differentiated and lateralized in the course of hominin evolution.

Definition

Language development is the process by which children come to understand and produce language to communicate with others, and entails the different components of phonology (sounds of a language), semantics (word meanings), grammar (rules on combining words into sentences), and pragmatics (the norms around communication).

Introduction

Language lies at the heart of humanity. The thousands of words and countless nuanced grammatical rules of language enable people to achieve a depth and breadth of social understanding and communication that is uniquely human. Without language, people would be left to rely on imprecise facial expressions and body movements to guess others' intentions, states, and emotions. People would be unable to pass along complex information and fully exploit the expertise of others. Language underpins the transmission of knowledge, traditions, expectations, and values across generations – it is the quintessential cultural tool. Without language, the world would be devoid of poetry, social media, poignant lyrics, folktales, historical documents, novels, and virtually all forms of written artifacts and oral tradition. The past would be lost and the future uninformed.

Developmental scientists have long marveled at children's ability to acquire language. Still, it takes many years for children to achieve the richness, complexity, and fluidity of adult language, and consequently to reap all of the advantages that language has to offer. Nonetheless, the communicative capacities of children fit their precise needs at each point in development. Children's language journey begins at birth (and even prenatally), extends over many years, and is supported by adult caregivers who provide social cues through face, voice, and body that help channel learning. These everyday social interactions are foundational to children's acquisition of the sounds, meanings, and rules of language.

This chapter highlights the functional adaptiveness, developmental changes, and social supports of early communication and language. We begin by illustrating the evolutionary roots to communication in nonhuman animals, followed by discussion of the development of communication in human infants. Next, we describe how caregivers and other adults facilitate infant language learning. Finally, we turn to functions of language in early childhood, with focus on the advanced language skills that undergird social interactions and pave the way for literacy development and school achievement.

Evolutionary Adaptiveness of Communication

Animals of all species communicate. Birds sound a variety of calls that convey meaningful information to their conspecifics (Marler and Slabbekoorn 2004). Bottlenose dolphins whistle to communicate with other dolphins (McBride and Hebb 1948). Whales use vocal calls and songs and nonvocal blows and slaps for reproductive and communicative purposes (Clark 1990). Monkeys howl and squids communicate by regulating the color of their skin (Mäthger and Hanlon 2006). These communications are vital to survival, with different sounds and behaviors conveying specific messages about threats to safety, food sources, and so forth. Over the course of development, the communication of the young grows in specificity and is shaped by adult input.

Specialization

Some species, including primates, birds, and some rodents, produce highly specialized vocalizations that aid survival (Vaughan et al. 2000; Perrins 2009). They produce sounds that are functionally referential, informing others about specific situations (Marler et al. 1992; Macedonia and Evans 1993). For example, songbirds, such as chickadees and thornbills, exhibit a variety of calls to alert conspecifics to potential danger or the availability of food (Perrins 2009). When predators appear, male chickadees shriek in a piercing high pitch and other chickadees freeze in position

until they hear the “all clear” call (Smith 1997). Adult birds alert their nestlings of predators, and the young quickly stop begging and crouch to remain safe (Halupka 1998). When food is present, chickadees chirp loudly, and their conspecifics swoop down to join in the feast. Similarly, prairie dogs produce unique sounds to communicate the size, speed, and color of approaching predators, and their conspecifics respond by diving into their burrows (Slobodchikoff et al. 2009). Bonobos alert others to the quality of food sources by barking loudly when they encounter highly preferred foods, such as bananas and grapes, but merely “peep-yelping” for less tasty foods, such as lettuce or peppers (Clay and Zuberbühler 2009).

Development

Animal young grow over time in their abilities to distinguish among different calls. In the first days following hatching, young black-capped chickadees increasingly respond to specific parental vocalizations by gaping to simulate feeding (Clemmons 1995). Not long after birth, infant vervet monkeys recognize the screams produced by their mothers, but do not yet react selectively to different calls (Cheney and Seyfarth 1980). Over the next several years, they respond accurately to alarm calls, for example by looking up to the sky in response to an “eagle” alarm and down to the ground in response to a “snake” alarm (Seyfarth et al. 1980; Seyfarth and Cheney 1986).

Young animals also produce increasingly complex and referentially accurate vocalizations with age. The vocalizations of young start out relatively imprecise but eventually convey situation-specific information. For example, young vervet monkeys sometimes mistakenly sound “snake” alarm calls to nonthreatening ground animals, or even to long twigs on the ground. With experience, vervet monkeys hone their screeches to dangerous contexts, alerting conspecifics to genuine predators (Seyfarth et al. 1980; Seyfarth and Cheney 1986). Similarly, young infant red-winged blackbirds beg for food by making peeping and chirping sounds – oblivious to their surrounds – which can place them at risk of attack by nearby predators (Redondo and Castro 1992).

Over time, the young learn to confine their begging sounds to times when predators are not around and survival is not at risk.

Social Support

What processes explain developmental changes in animals’ understanding and production of communicative signals? Feedback from and exposure to the vocalizations and behaviors of conspecifics are fundamental to social integration and survival. Notably, adults shape the sounds that young produce through physical proximity and contingent feedback. Chickadee parents respond to nestling begging sounds with alarm calls in attempts to quiet their young and avoid attracting predators (Madden et al. 2005). When vervet monkey mothers are nearby, their young respond with calls that more closely match those of adults than would be seen if mothers were far away (Seyfarth et al. 1980). When vervet monkey infants hear a playback alarm, they are more likely to respond appropriately if they look (versus do not look) to an adult first (Seyfarth and Cheney 1986). Adult monkeys are more responsive to their young’s accurate than inaccurate predator calls (Seyfarth and Cheney 1986).

The refinement of bird songs in the presence of conspecifics further illustrates the power of social feedback. Young male cowbirds sing stereotyped songs earlier and show higher song potency when females stroke their wings or gape in response to their songs (King et al. 2005). Male cowbirds repeat and retain songs that elicit positive feedback from females at three times the rate seen for songs that do not experience this feedback (West et al. 1998). In fact, young male cowbirds often fail to communicate effectively, sing to, and mate with females later in life after being reared in isolation (West et al. 2003).

Communication and Language in Human Infants

The adaptiveness and developmental changes of animal communication likewise characterize that of human infants and children. However, language in humans contains impressively unique

features. People understand and produce an astounding number of words and apply complex grammatical rules to the combination of those words relatively seamlessly. In terms of sheer vocabulary size, native English-speaking 1st graders have an estimated vocabulary size of 10,000 words, which increases to 40,000 by 5th grade (Anglin 1993). Moreover, humans can produce and understand an infinite number of word combinations, including nonsensical, yet otherwise interpretable sentences such as “the purple dog is sitting on the velvet branch.” What is perhaps most notable about the human capacity for language is children’s remarkable facility at learning under natural conditions: Children in all cultures, under strikingly different rearing contexts, become skilled consumers and producers of the language(s) to which they are exposed. How do they accomplish this feat?

Building on a dynamic-systems approach to language, a confluence of interacting factors, internal and external to the child, pave the way for language learning (Smith and Thelen 1993; Smith 2013). From the first days of life, infants are immersed in an abundantly rich multisensory environment that elicits attention and spurs engagement with the world. And, well before infants understand or produce conventional words, they emit sounds, facial expressions, and body movements that are salient to adults who respond with prompt, attuned behaviors. These early social interactions are building blocks to language and critical to survival. In this section, we describe developmental changes in infants’ communicative skills and experiences, and the ways that adults facilitate the language development of infants and toddlers.

Communicating Through Gaze, Gestures, and Emotions

Infants are astute observers of the social world. Prelinguistic infants are highly sensitive to cues in people’s voice, face, and body movements (Bloom 2000; Brooks and Meltzoff 2008; Caza and Knott 2012; Singh et al. 2002), and show impressive gains in their abilities to interpret and respond to these signals over the first 2 years (e.g., Frank et al. 2009; Suanda et al. 2017). Moreover,

well before infants speak, they produce multi-modal signals through gazes, facial expressions, body movements, and manual actions that communicate to the people around them. Over the course of the first year, infants grow in their abilities to follow and pinpoint the target of people’s gaze, respond to gestures like points, and discriminate and understand emotions expressed in people’s faces and bodies.

Following Gaze

Gaze following is central to learning language. Gaze provides information about peoples’ attention and intention – such as when mom looks at an animal in the zoo and exclaims, “Look, a monkey!”, and baby traces her gaze to land on the monkey. Yet, accurate gaze following is not automatic, and it takes several months for infants to identify the target of a person’s interest. Infants begin following gaze to distant targets as early as 6 months (Butterworth and Itakura 2000; Butterworth and Jarrett 1991), and reliably follow gazes that are matched to the looker’s body orientation between 7 and 9 months (Woodward 2003). Later in the first year, around 9–11 months of age, infants shift from simply following an adult’s head orientation to connecting a person’s gaze with the environmental referent (Brooks and Meltzoff 2005). By around 12 months of age, infants follow an adult’s gaze to locations outside their field of view (Moll and Tomasello 2004). During play interactions, infants look at the same objects as their mothers (Deák et al. 2014), and are especially adept at following gazes that are combined with salient cues such as object manipulation or verbalizations (Deák et al. 2017). The importance of gaze following for language development is evidenced by associations between early gaze following and vocabulary size (Brooks and Meltzoff 2005).

Understanding and Producing Gestures

Like gaze, gestures (particularly points) alert people to the referents of talk. Infants at first track a pointing finger by looking at the finger itself, only to later appreciate that a person’s outstretched finger designates an object of interest (Woodward and Guajardo 2002). By about 12 months of age,

infants successfully look where others point (Schaffer 1984; Woodward and Guajardo 2002), and begin pointing themselves to request assistance (protoimperatives) and alert others to interesting things (protodeclaratives) (Bates et al. 1975; Butterworth and Morissette 1996; Cochet and Vauclair 2010). Declarative pointing is thought to reveal an infant's understanding of others as intentional agents (e.g., Liszkowski et al. 2004; Tomasello et al. 2007) and is considered a precursor to language development (e.g., Iverson and Goldin-Meadow 2005; Rowe and Goldin-Meadow 2009; Tomasello et al. 2007). Infants who produced more gestures at 14 months understood more words at 54 months (Rowe and Goldin-Meadow 2009).

Understanding Others' Emotions and Behaviors

Infants' abilities to discriminate among emotions and discern the meaning of emotions are core to social interactions. A smiling face conveys something quite different than does a furrowed brow, and effective communication rests on attuning to the often-subtle emotional cues in a person's face, voice, and body. By 3 months of age, infants can discriminate among mothers' happy, sad, and angry facial expressions (Haviland and Lelwica 1987). At 4 months of age, infants prefer to listen to "infant-directed speech" (i.e., speech characterized by a high pitch and sing-song intonation) rather than adult-directed speech (Fernald 1985), perhaps because positive affect is inherent in most baby talk (Singh et al. 2002). Around the same age, infants look preferentially at their mothers' sad or happy facial expressions that match the tone of mothers' vocal expressions, suggesting they have extracted meaning from the intermodal affective displays (Kahana-Kalman and Walker-Andrews 2001).

Infants' growing emotional understanding allows them to act in line with the valence of social messages. For example, in the famous visual cliff paradigm, 14-month-old infants referenced mothers' facial expressions of fear or happiness when deciding whether or not to cross an ostensibly dangerous cliff (Sorce et al. 1985). The majority of infants crossed when mothers posed happy expressions, whereas no infants

crossed when mothers posed fearful expressions (Sorce et al. 1985). Similarly, 12-month-old infants used maternal vocal and facial cues to determine whether to approach an object for play. Infants responded to their mothers' fearful vocal emotional signals by looking at their mothers longer and showing less proximity to novel toys than infants in a neutral voice condition (Mumme et al. 1996), and displayed avoidance and negative affect after viewing a female stranger's emotional reactions toward novel objects on television (Mumme and Fernald 2003).

Over the second year of life, infants increasingly appreciate that other people can be valuable sources of information, and use social information selectively to resolve ambiguity. For example, 18-month-old infants used verbal, facial, and gestural information provided by their mothers when deciding whether to walk down slopes that were uncertain in their risk, but ignored mothers' messages when slopes were clearly easy and clearly dangerous to descend (Tamis-LeMonda et al. 2008).

The World of Language: Communicating Through Sounds, Words, and Sentences

Infants' growing skills in gaze following, gestural communication, and emotion understanding provide a springboard for learning the sounds (phonemes), word meanings (semantics), grammatical rules (syntax), and social norms (pragmatics) of the language(s) to which children are exposed.

Sounds and Intonation Patterns

Over the first months of life, infants increasingly hone in on the sounds (phonemes) and intonation patterns of their native language(s) (Eimas et al. 1971; Kuhl 1979, 2004; Mehler et al. 1988; Werker and Tees 1984). Babies as young as 2 months of age prefer speech to nonspeech sounds (Vouloumanos and Werker 2004) and respond to the prosody contours of their language (Mehler et al. 1988). Even before they develop grammatical knowledge, English-speaking infants can differentiate the prosody of questions from that of declarative statements (Soderstrom et al. 2011). Infants detect the phonemes of all languages at first, but with time, channel their

attention to the sounds of their native language (Werker and Tees 1984).

Infants also produce a rich variety of sounds to communicate with others (e.g., Oller et al. 2013), progressing through a universal sequence from prelinguistic vocalizations to producing speech over the first 2 years of life (Ferguson et al. 1992). The early cries, grunts, and coos of newborns are salient to parents, who vigilantly respond by feeding, changing, and comforting their infants. Between approximately 5 and 10 months of age, infants' coos develop into strings of consonant-vowel syllables known as canonical babbling, which begin to approximate words. Infants' babbles gradually take on the sounds, rhythm, and intonation patterns of their home language. French adults, who listened to the babbling of a French 8-month-old and an 8-month-old from either an Arabic- or Cantonese-speaking family, were better than chance at identifying which baby was the French one in each pair (de Boysson-Bardies et al. 1984).

Understanding and Producing Words and Sentences

Young infants are able to extract regularities in their environments, which sets the stage for distinguishing familiar phoneme pairings (or "words") from unfamiliar "nonwords" (Saffran et al. 1996). By 4.5 months of age, infants recognize the sound pattern of their own name (Mandel et al. 1995), and by 6 months of age can segment individual words out of speech streams (Bortfeld et al. 2005; Johnson et al. 2014). Infants as young as 6–9 months of age begin connecting words to their referents, often learning the meanings of food words and body parts early on, likely because these words are embedded in repeated everyday activities (Bergelson and Swingley 2012). Around the time that infants produce their first words (~12–14 months of age), they can exploit statistical regularities to map novel words to novel objects in laboratory tasks (Smith and Yu 2008). Over the course of the second year, infants grow in their receptive vocabularies (Hoff 2009) and can follow simple instructions ("Come here!") and understand simple "Wh"-questions ("Where's the rabbit?").

Notably, infants understand many words and phrases several months earlier than they are able to produce them. Infants typically produce their first words around 12–13 months of age (Hoff 2009), with first words typically being the names of objects (Gentner 1982; McDonough et al. 2011). Midway through the 2nd year, infants experience a "vocabulary spurt," producing new words at an impressive rate (Barrett 1985), and soon thereafter combining words into simple sentences (Brown 1973). Advances in grammar and vocabulary enable infants to regulate the actions of their caregivers, for example, through phrases such as "want ball" or "more cookie."

Impressively, infants' first word combinations adhere to the principles of word order seen in their language and can be traced to the months of learning that occurred prior to the first expression of these simple "sentences." To illustrate, well before infants combine words in sentences, they attend to the word order of spoken sentences (Golinkoff et al. 1987; Hirsh-Pasek and Golinkoff 1996): They show comprehension of subject and object questions (e.g., *What hit the keys?* and *What did the book hit?*; Seidl et al. 2003), and process words faster in grammatically correct than incorrect sentence constructions (i.e., looking to the target faster when hearing "Can you see *the* ball?" than hearing "Can you see *and* ball?"; Kedar et al. 2006; see Golinkoff et al. 2013 for a review). Infants can also identify target actions for novel verbs (e.g., "The duck is kradding the bunny") by using their syntactic knowledge (e.g., Naigles 1990), a process referred to as syntactic bootstrapping (Gleitman 1990). As children further develop semantic and grammatical skills, they become increasingly adept at decontextualized speech (talk about the "then and there") and narrative constructions during play and storytelling.

Supportive Role of Caregivers

Children's rapid and impressive gains in language over the first years of life are, at least in part, facilitated by the rich language input and supportive environments provided by caregivers and

other adults. Just as cowbirds' contingent wingstrokes shaped the onset of singing and promoted song potency in the young, human adults support infants through contingent social interactions and by providing concomitant social cues to the referents of their talk. Adults support children's language development by introducing new words, producing exaggerated actions (motionese) and intonation patterns, responding contingently to infant behaviors, and shifting to increasingly complex language as children develop.

Diversity in Language Input

Adults provide infants with a rich and steady stream of interesting words, phrases, and accompanying actions for infants to process. During object play, caregivers describe and label objects that pique infants' interest (Goldstein and Schwade 2010). Mothers' didactic language promotes infants' vocabulary development (Tamis-LeMonda et al. 2012a). Adults repeat words and phrases when speaking to infants, and infants learn to connect sounds to concepts after only a few repetitions, known as "fast-mapping" (Hollich et al. 2000).

Temporal Contingency

Caregivers support infants' understandings of the natural ebb and flow of conversations by tailoring the pace and contours of their speech. Mothers take pauses after speaking to allow time for infants to respond, and they promptly respond to infant gestures, touch, and vocalizations (Jasnow and Feldstein 1986; Hsu and Fogel 2003; Tamis-LeMonda et al. 2013). Infants come to understand the flow of everyday conversations as they learn to take turns conversing with partners (Gratier et al. 2015). Parents' contingent responsiveness fosters early language development (Tamis-LeMonda et al. 2014a, 2006), and relates to infants' own contingent responsiveness to the speech acts and gestures of their mothers (Kuchirko et al. 2017).

Infant-Directed Speech

Parents use a special register of speech characterized by slow pace, short and simple sentences, variable pitch, and high redundancy when talking

with infants (Fernald 1985). Infant-directed speech provides a richly informative context for infants to learn new words (Saint-Georges et al. 2013). The rich prosody cues of infant-directed speech help infants parse units and patterns in speech streams that later become words and grammatical structures (Ma et al. 2011). Infant-directed speech also facilitates infants' long-term memory of words (Singh et al. 2009).

Gestures and "Motionese"

Adults put on a show for infants, sparking infant attention and interest through their enthusiastic and exaggerated manual actions. During object play, mothers direct and redirect infants' attention by pointing, gesturing, and handling objects (Deák 2017). Adults use special infant-directed gestures or "motionese" to communicate with infants (Brand et al. 2002, 2007). Motionese, especially when paired with infant-directed speech, makes adult speech exciting and accessible to the infant, which may explain why infants imitate actions contained in motionese faster than those contained in adult-direct action (Williamson and Brand 2014). Indeed, "acoustic packaging" – the pairing of language input with gestures and other actions – helps infants parse information from speech streams (Hirsh-Pasek and Golinkoff 1996; Wrede et al. 2013) and supports vocabulary learning (Rowe 2000; Rowe et al. 2008).

Increasing Language Demands

Adults are highly sensitive to developmental changes in infant language skill, and tailor their language in line with children's changing skills. Parents use fewer words and less grammatically complex language when infants' language skills are emerging, and increase the amount and diversity of language input as infant language improves (Tamis-LeMonda et al. 2012b). As infants master a growing set of words, parents introduce new words and respond more to children's use of novel words (Masur 1997), and direct an increasing number of questions to their infants (Bornstein et al. 2008). Paralleling infants' transition from using gestures to using words to communicate during the 2nd year of life, mothers decrease their responses to infant gestures and increase

their responses to vocalizations (Tamis-LeMonda et al. 2013).

Language Functions in Early Childhood

Over the course of toddlerhood and early childhood, children show extraordinary gains in articulation, vocabulary, grammar, and narratives. By the time U.S. children reach first grade, they understand between 5,000 and 20,000 words (Moats 2001), can apply grammatical rules to the construction of complex sentences, and engage in elaborate conversations with others (Hoff 2013). At the same time, children venture out of the home into new caregiving and learning contexts that offer unique opportunities to acquire and practice language. Growth in language skills over this period helps children regulate theirs and others' behaviors and emotions, construct elaborate and decontextualized narratives to talk about the past and future, engage in imagination and play, and establish positive relationships with teachers and peers. As such, language provides a vital foundation to cognitive, social-emotional, and literacy developments in early childhood (e.g., Astington and Jenkins 1999; Hoff 2013; Marchman and Fernald 2008; Snow et al. 1998; Tamis-LeMonda et al. 2014b).

Speech to Regulate Behaviors and Emotions

Language supports young children's efforts at self-regulation. Vygotsky (1934/1986) referred to words as symbols or mental tools for manipulating thoughts and behaviors. The development of self-regulation is thus a process in which children internalize caregivers' regulatory speech and strategies (Kopp 1982; Vygotsky 1934/1986). Thus, the richer children's symbolic repertoire (i.e., language skill), the more tools they have at their disposal for regulating their behaviors (Vallotton and Ayoub 2011), as evidenced in associations between language skills and self-regulation in toddlerhood (e.g., Vallotton and Ayoub 2011) and early childhood (e.g., Astington and Jenkins 1999; Cutting and Dunn 1999). Language likewise enables children to verbally communicate their emotions and internal states in

socially appropriate ways (Cole et al. 2010), and to engage in self-managing talk (Eisenberg et al. 2005). Consequently, preschoolers' language skills relate to their ability to cope with frustrating situations (Stansbury and Zimmerman 1999), and conversely, language impairment portends difficulty in emotion regulation (Fujiki et al. 2002).

Decontextualized Speech and Narratives: Time and Space Travel

From infancy through the early childhood years, children's speech shifts from a focus on the highly contextualized "here and now" to the increasingly decontextualized "there and then." By 4 years of age, children are proficient at mentally representing objects, events, and internal states of people and story characters that are not immediately present (see Flavell and Miller 1998, for review). Decontextualized discourse conveys meaning through linguistic devices such as grammar and vocabulary, rather than extralinguistic devices (e.g., gesture), contextual cues (e.g., an object), and shared knowledge (Pellegrini 1985; Scott 1994; Westby 1991). As such, decontextualized discourse is characterized by "literate language features," involving elaborate noun phrases, adverbs, conjunctions, and mental (e.g., think) and linguistic (e.g., say) verbs (Greenhalgh and Strong 2001; Pellegrini 1985), building blocks to literacy development (Curenton and Justice 2004; Pellegrini 1985; Scott 1994; Snow 1991; Westby 1991).

Development in decontextualized language skills enable young children to construct elaborate narratives and revisit the past through reminiscing (discussing shared experiences) or recounting (discussing unshared experiences). However, narrative skills develop over several years, and at first require a lot of scaffolding. At the end of the second year of life, children begin to refer to past events, initially with much prodding and support by adults (Eisenberg 1985; Sachs 1982). At 2 years, children often talk about negative past events, especially injuries (Miller and Sperry 1988), but over the next few years, children tell longer and more sophisticated personal narratives, and increasingly respond to the narratives of their peers (Umiker-Sebeok 1979). The personal narratives of North

American, Caucasian, English-speaking children developed from “Two-Event” narratives at 3½ years, to “Leap-Frog” narratives (i.e., stories that omitted key events) at 4 years, to “End-at-High-Point” narratives (i.e., lacking a resolution) at 5 years, to the final “Classic Narrative” by age 6 years (McCabe and Peterson 1991; McCabe and Rollins 1994; Peterson and McCabe 1983). Children’s advances in narrative skills reverberate across several developmental domains: Reminiscing, for example, solidifies social bonds (Fivush et al. 1996; Nelson 1993; Reese and Brown 2000), and individual differences in narrative skills predict later academic achievement (Feagans and Appelbaum 1986; Feagans and Short 1984; O’Reilly et al. 2004).

Language in Imagination and Pretend Play

Children’s blooming of decontextualized language and the elaboration of narratives allow imagination and pretend play to take off. From the pretend play scenarios of toddlers, to the personification of objects by 3-year olds (such as treating a toy animal as a living, conversational partner), to the creation of imaginary companions, young children enter a fictional world where all things are possible (Singer and Singer 2006). Language is an integral component to the emergence of imagination and pretend play (Andresen 2005; Bruner 1983; Bergen 2002; Singer and Singer 2006). For example, role play – which involves pretending to be the characters of imagined plots – requires decontextualized forms of language to establish the context and generate an altered reality (Andresen 2005). Language helps construct the frame for imaginative role play, as when children establish shared goals through metacommunication (e.g., “Let’s pretend...”; Andresen 2005).

Relationships with Teachers and Peers

The school context allows young children to develop close and meaningful relationships with people outside the family, namely teachers and peers, and language is a primary mechanism for establishing and fostering those relationships (Pence and Justice 2007). It is thus unsurprising that children who exhibit language deficits or

weaknesses in communication sometimes have difficulty developing positive relationships at school (Justice et al. 2008; Rudasill et al. 2006). Children with underdeveloped language skills are more withdrawn, less social, exhibit lower self-esteem, and have more difficulty regulating their emotions than do their peers with strong language skills (Fujiki et al. 1999, 2002; Jerome et al. 2002). These social difficulties could undermine the quality of teacher-child relationships (Howes et al. 2000). Furthermore, children with poor language skills, especially boys, tend to display disruptive behaviors (e.g., Arnold 1997), presumably due to frustration in learning situations (Homrok and Arnold 1995), and disruptive behavior in turn leads to peer rejection (Stowe et al. 2000).

Role of Educators: Language in Educational Settings

Early childhood educators, with whom children spend a significant portion of time during the preschool and early school years, tremendously influence children’s language development. Teachers continually interact with children during circle time, center and playtime, meal and snack times, and book reading (Massey 2004; Pianta and Hamre 2009), thus constituting “the main conversationalists, questioners, listeners, responders, and sustainers of language development and growth in the child-care center or classroom” (Genishi 1988, p. 3).

As might be expected, the quantity and quality of teachers’ language interactions with children powerfully shape children’s skills in language and other domains. Teacher-child interactions that involve cognitively challenging conversations; encourage higher-order thinking skills; and contain a diverse vocabulary relate to children’s cognitive, language, and literacy outcomes (Dickinson and Smith 1994; Mashburn et al. 2008). Cognitive challenging conversations encourage children to provide explanations and personal narratives, analyze experiences, draw inferences, and share opinions and ideas (Smith and Dickinson 1994; Luo and Tamis-LeMonda 2017), and thus support children’s skills decontextualized talk about past and future events (Massey 2004).

Conclusion

Language is uniquely human. Yet, the functions of language and the development of language skills embody the evolutionary adaptiveness of communicative behaviors observed in non-human animals. Throughout evolutionary history, nonhuman animals and humans alike have developed specialized and sophisticated communicative strategies to relay their needs, alert others to danger and resources, and build and maintain relationships – skills that are crucial to survival and social integration. In humans, however, the unrivaled richness and complexity of language make its achievement nothing short of extraordinary. How do the babbling blunders of young infants develop into the decontextualized conversations and imaginative play scripts of young children?

Early on, infants are able to detect statistical regularities and environmental contingencies, requisites for building meaning out of input and resolving referential ambiguity (Tamis-LeMonda and Bornstein 2016). Additionally, infants' interest in and attention to the messages conveyed in others' face, hands, body, and prosody cues in speech are seeds to the understanding and production of conventional words, sentences, and ultimately elaborate stories. But, beyond these child contributions, parents, caregivers, and other adults facilitate language learning at all points in development. Adults not only provide contingent language in response to children's behaviors, but also accommodate young children's needs through infant-directed speech and gestures and by tailoring the complexity of their lexical and grammatical input to children's communicative development. As children become increasingly competent language users, adults "up the ante" by engaging them in interactions that involve and promote higher-order thinking and increasingly sophisticated language functions and forms. In short, animal young and human children develop species-specific communicative skills with the support of adults. As the young mature into competent communicators, they will one day support the development of communication and language in future generations.

Definition

Language dysfunction refers to abnormalities in processing of linguistic information.

Introduction

Language is a complex cognitive function that involves multiple levels of linguistic representation, including phonology, morphology, syntax, semantics, and discourse. A huge number of computations are required to sustain and integrate this multilevel information. Language disturbances may arise due to an inability to build or analyze linguistic representations or because of disruption to the computations intrinsic to language function. Since language functioning requires other cognitive domains (e.g., memory, attention, executive function, control processes), language disturbances may appear as a result of dysfunction in these other domains. As an example, sentence comprehension is supported by various memory mechanisms; if the memory demands that are required for assignment of syntactic structure and inference of sentence interpretation based on that structure are not met, there will be

comprehension failure (Caplan and Waters 2015). Given the complexity of language and its interactions with other cognitive domains, it is not surprising that language implicates a wide range of brain areas. Lesions in these brain areas and their anatomical connections lead to language impairments.

Many disciplines study language dysfunction. While neurologists are mainly concerned with associated brain damage, speech pathologists focus on developing speech/language therapies, neuropsychologists investigate residual functional abilities after brain damage, and neurolinguists test hypotheses on patterns of impairment related to specific language components. For a cognitive neuroscientist, the biggest challenge is to find out where exactly in the massive number of computations that enable language function the changes that cause dysfunction occur and how these computational changes map onto brain organization.

Aphasia

Aphasia is an acquired language disorder caused by brain damage. It affects language production and comprehension at the level of single words, sentences, and discourse across different modalities (e.g., spoken language, written language, sign language). Aphasia is present in about 40% of stroke cases, at least in the first few months following the stroke, with the aphasic symptoms persisting in many patients. In addition, aphasia is also common in traumatic brain injury and tumor patients. These conditions do not create ‘neat’ lesions and typically result in complex patterns of language breakdown (Caplan 1995).

Transient language disturbances may appear as a result of epilepsy, migraine headache, drug and alcohol abuse, and sleep deprivation. In contrast, progressive language deterioration is an early symptom of an atypical variant of initially focal fronto-temporal degenerative disease known as primary progressive aphasia. Furthermore, severe language abnormalities characterize later stages of multiple sclerosis, Alzheimer’s disease (AD), Creutzfeldt-Jakob disease, and other progressive

diseases of cortical structures in which many other behavioral and neurologic abnormalities are more salient than language impairments (Benson and Ardila 1996). Language disturbances are common in psychosis, in particular schizophrenia, and in some mood disorders, such as mania.

The extent and type of language disturbances and the brain potential to recover language depend on the lesion type, size, and location. Functionally, the brain can adapt better to slow-growing lesions, such as low-grade glioma, than to sudden lesions such as those caused by stroke (Desmuget et al. 2007). Some evidence suggests that smaller post-stroke lesions are associated with language reorganization in perilesional areas and with better prognosis than larger lesions, which typically involve contralateral homologous areas and have a poor prognosis (Karbe et al. 1998). Other evidence indicates that post-stroke language recovery involves three distinct phases, characterized by a hemispheric shift of function. In the acute phase (~2 days post-stroke), the areas surrounding the lesion show almost no activation; there is also no marked task-related activation in the opposite hemisphere. The beginning of language recovery, which marks the subacute phase (~2 weeks post-stroke), is associated with activation of homologous areas in the right hemisphere. Further recovery of language during the chronic phase (~4–12 months post-stroke) is associated with normalization of activation and a functional shift to the left hemisphere (Saur et al. 2006). Taken together, these findings suggest that a range of brain areas in both cerebral hemispheres contribute to language recovery after stroke, and that a case of chronic aphasia with dominant right hemisphere functionality would be associated with poor recovery. However, the debate regarding whether the right hemisphere supports compensatory, suboptimal, or maladaptive processes in language recovery after stroke has not been settled.

Current models of language dysfunction and the neural basis for language have inherited some basic ideas from nineteenth-century aphasiologists, who established that language is left-lateralized and correlated the site of a lesion with a specific type of language disorder. In the 1860s, Paul Broca recognized that injury in the

inferior frontal gyrus of the left cerebral hemisphere caused a speech deficit, which is known as motor, expressive, or Broca's aphasia. Subsequent developments in aphasiology include Carl Wernicke's finding that damage to the left superior temporal region causes a comprehension deficit, combined with a type of speech production impairment different from the one described by Broca. This type of impairment is known as sensory, receptive, or Wernicke's aphasia (Kljajevic 2014).

Considering that the two types of language disorders – motor and sensory aphasia – followed damage to the left inferior frontal region and left superior temporal region, respectively, Wernicke hypothesized that damage to the arcuate fasciculus, i.e., the white matter tract connecting the two regions, would result in a third type of aphasia, *Leitungsaphasie* or conduction aphasia. Patients with this type of aphasia would have an impaired ability to repeat speech, but spared abilities to produce and comprehend speech. Conduction aphasia was clinically confirmed by Ludwig Lichtheim, who further developed Broca–Wernicke's model and proposed additional aphasic syndromes. The Broca–Wernicke–Lichtheim model was further developed by Jules Dejerine in the late nineteenth century and Norman Geschwind in the mid-twentieth century, who recognized the importance of the left inferior parietal lobe for language. Although the model has been criticized on various grounds, some of its main principles are reflected in current models of functional neuroanatomy of language, such as relative functional specialization of brain areas and the importance of anatomical connectivity for language function (Kljajevic 2014).

There are many classifications of aphasia. Assuming the classical approach, the following seven aphasic syndromes are typically discerned: Broca's aphasia, Wernicke's aphasia, conduction aphasia, transcortical motor aphasia, transcortical sensory aphasia, global aphasia, and anomic aphasia. The aphasic syndromes can be roughly grouped into non-fluent (Broca's, transcortical motor, global) and fluent (Wernicke's, conduction, transcortical sensory, anomic) based on the impression of fluency in aphasic speakers' overt speech production. Spontaneous speech is one of the

features used in the classical approach to assign a person with language disturbances to one of the aphasic syndromes. Other features include auditory comprehension, verbal repetition, and naming abilities, as well as the lesion site.

Broca's aphasia is characterized by non-fluent, effortful, and impoverished speech, with omission of function words and inflection. The type of erroneous speech output in which function words and inflection are omitted is known as agrammatism. Furthermore, speech output in persons with Broca's aphasia is reduced to short phrases, containing two to three words. Due to agrammatism and decreased verbal output, the Broca's aphasic speech pattern is reminiscent of a telegraphic style. Another feature of this type of aphasia is more impaired production of main verbs than nouns, which is in contrast to Wernicke's aphasia, where production of nouns is more impaired than production of verbs. Other features of speech output in Broca's aphasia include impaired melodic line and intonation as well as semantic and phonemic paraphasias (i.e., target words and syllables are substituted with incorrect words and syllables). Speakers with Broca's aphasia also have impaired repetition of words and phrases, their naming abilities are disrupted, and they can have impaired reading and writing. Comprehension of words and phrases is generally preserved, but comprehension of longer and syntactically more complex sentences is impaired. For instance, persons with this type of aphasia comprehend simple active (e.g., 'The boy kissed the girl') or subject relative sentences (e.g., 'The boy who kissed the girl is tall') well, but they find passive (e.g., 'The boy was kissed by the girl') and object relative sentences (e.g., 'The boy who the girl kissed is tall') difficult to comprehend; they also have reading and writing deficits.

Wernicke's aphasia is characterized by fluent but meaningless or 'empty' speech, which may be produced at a normal or rapid rate. The common feature of verbal output in this syndrome is 'press of speech,' which is known as logorrhea. Spontaneous speech of persons with Wernicke's aphasia is characterized by paraphasias, neologisms, and gibberish output termed jargon aphasia. Whereas

Broca's aphasic speakers omit function words and inflection, persons with Wernicke's aphasia select wrong function words and inflection, along with incorrect verb tenses, conditional clauses, and word order. This type of erroneous speech output is known as paragrammatism. Since persons with Wernicke's aphasia are unable to monitor their speech output, they remain unaware of the deficit and thus do not attempt to correct their speech errors. However, their spontaneous speech indicates a relative preservation of syntactic structure. Another key feature of Wernicke's aphasia is severe impairment of auditory comprehension. Verbal repetition, reading, and writing are also deficient, as is naming, and phonemic and semantic prompting does not help.

Conduction aphasia is a fluent syndrome in which there is a marked inability to repeat phrases and sentences, somewhat impaired naming, reading and writing, but relatively spared auditory comprehension and spontaneous speech.

Transcortical motor aphasia is similar to Broca's aphasia. This non-fluent syndrome is characterized by reduced and impoverished speech output, relatively preserved auditory comprehension – except for long and syntactically complex sentences – and impaired naming, reading, and writing. Unlike in Broca's aphasia, repetition of phrases and sentences is relatively preserved in this syndrome.

Transcortical sensory aphasia is similar to Wernicke's aphasia: it is a fluent syndrome with marked auditory comprehension impairment combined with deficits in naming, reading, and writing. However, verbal repetition is preserved in this syndrome.

Global aphasia is a non-fluent syndrome. Of all of the types of aphasia, global aphasia involves the most severe impairments at all levels of language. Speech production is typically reduced to stereotypical and automatic expressions. Auditory comprehension is severely impaired and may be reduced to occasional comprehension of single words. The abilities to repeat words and phrases, name objects, and read and write are absent. The prognosis is generally poor and only some cases evolve to a less severe type of aphasia such as Broca's.

Anomic aphasia is a fluent syndrome characterized by a word-finding difficulty. Auditory comprehension and repetition are typically spared, but mild impairment in reading and writing may be present. Nevertheless, its separate syndrome status has been debated (Benson and Ardila 1996) given that anomia, i.e., difficulty with word retrieval, is a feature that is to some extent present in all types of aphasia.

Crucially, the syndrome approach postulates that each type of aphasia is associated with a lesion in a specific brain area or with a disruption to anatomical connections between the relevant areas. According to this approach (i) Broca's aphasia is associated with damage to Broca's area, i.e., the left inferior frontal region (Brodmann areas 44 and 45); (ii) Wernicke's aphasia follows damage to Wernicke's area, i.e., the left posterior superior temporal region (Brodmann area 22); (iii) conduction aphasia is associated with damage to the left arcuate fasciculus; (iv) transcortical motor aphasia is associated with lesions in the left frontal areas, anterior to Broca's area; (v) transcortical sensory aphasia follows damage to the left parietal-temporal-occipital junction; (vi) global aphasia follows left fronto-temporo-parietal lesions, i.e., the entire perisylvian region; and (vii) anomic aphasia follows damage to the left inferior parietal region.

However, language is much more distributed in the brain than previously thought (Price 2012). It has also become clear that an aphasic syndrome can have different localizations and that different types of aphasia can follow damage to the same brain area. For instance, growing evidence suggests that damage to Broca's area is associated with only transient language disturbances and that Broca's aphasia requires larger lesions, which often involve the underlying white matter (Mohr et al. 1978). In addition, Broca's area itself is functionally not homogeneous, and thus it remains unclear which specific aspect of language this particular region fails to support in Broca's aphasia. Similarly, lesions associated with conduction aphasia rarely affect only the arcuate fasciculus (Damasio and Damasio 1980); damage to this white matter

tract does not necessarily cause conduction aphasia, and this type of aphasia may occur due to damage to other brain areas, sparing this particular white matter tract.

The picture becomes even more complex when deep gray matter structures are considered. As an illustration, lesions in the basal ganglia have been associated with Broca's, Wernicke's, transcortical motor, conduction, global, and anomic aphasia, as well as with no aphasia at all (Nadeau and Crosson 1997). In addition to illustrating a more general difficulty in assigning a certain type of aphasia to a specific lesion site, this finding also suggests that language disturbances of the classic aphasic syndromes may be associated with damage to subcortical structures. Still, subcortical aphasias, such as striato-capsular aphasia, thalamic aphasia, and aphasia associated with white matter disease (e.g., in multiple sclerosis) (Benson and Ardila 1996), appear to be even more difficult to define and categorize.

Apart from poor lesion-function mapping, the syndrome approach to aphasia has been criticized on other grounds: the syndromes are linguistically underspecified (e.g., comprehension is a set of complex processes, not a monolithic task), the same symptoms appear across different syndromes (e.g., anomia, paraphasias), and there is a variation in patterns of aphasic disturbances, both individually and cross-linguistically (Kljajevic and Murasugi 2010). In addition, aphasia evolves. For example, global aphasia evolves to Broca's aphasia, while Broca's, Wernicke's, and conduction aphasias often reduce to anomic aphasia. The instability of aphasic syndromes is probably best illustrated by symptom variation within a single patient, which can occur even within a single testing session, as well as by variation in symptoms in different patients with similar lesions. Regardless, the aphasic syndromes remain useful to clinicians as a quick summary of the most salient, even if not very precisely defined, features of language disturbances in individual cases. However, researchers are developing more sophisticated linguistic descriptions of aphasic language, often using neuroimaging methods to test hypotheses on specific language computations.

Language Disorders Following Right Hemisphere Damage

Most language functions, including the lexicon and grammar, are lateralized to the left hemisphere in more than 95% of right-handed persons and about 70% of left-handed persons. Thus, right-handed persons typically develop aphasia after left-hemisphere lesions. Left-handers often develop aphasia after lesions in the right hemisphere, but a proportion of this population have aphasia after left-hemisphere damage. Patients with atypical lateralization for handedness appear to have less severe aphasia than those with typical handedness.

Early evidence on right hemisphere involvement in language in right-handed persons comes from studies using the intracarotid amobarbital injection technique (or ‘Wada test’), which is a procedure that anaesthetizes and thus temporarily blocks functionality of one hemisphere. These studies showed that the anaesthetized right hemisphere caused additional difficulties in speech production in persons with left hemisphere damage. Additional early evidence on the role of the right hemisphere in language comes from studies with split-brain patients (Gazzaniga et al. 1984). (These are patients who had resection of the corpus callosum, i.e., the white matter tract connecting the left and right cerebral hemisphere, to relieve severe epilepsy not responding to medications.) These studies showed that in some cases the isolated right hemisphere retained a limited capacity for language, such as the ability to comprehend and read words, and to understand simple sentences, but not those that are syntactically complex (e.g., ‘The boy that was kissed by the girl smiled’). Subsequent findings have suggested that only a small portion of split-brain patients retains right hemisphere language.

More recent studies use neuroimaging methods, such as functional magnetic resonance imaging (fMRI) and functional transcranial Doppler sonography, to record brain activation in the cerebral hemispheres and calculate a lateralization index. These methods assess laterality effects based on the extent of activation associated with performance of a task. Functional neuroimaging studies with right-handed aphasic patients who

had a left-hemisphere stroke suggest involvement of the right hemisphere during language recovery. This evidence typically points to rather limited functional support provided by the right hemisphere to ‘core’ language functions (Karbe et al. 1998; Saur et al. 2006) and some researchers associate the right hemisphere involvement in language recovery after left hemisphere stroke with domain-general attentional processes rather than with language per se.

The neurobiological basis of a differential hemispheric role in language is currently not well understood, although some researchers have proposed explanations in terms of neuroanatomical asymmetries between the two hemispheres (e.g., asymmetry in the planum temporale). Current models of language organization in the brain postulate that the right hemisphere supports some language-related functions either in concert with the left hemisphere, as in speech perception, or as the dominant hemisphere for that specific function, i.e., unilaterally, as in communicative and emotional prosody, discourse production and comprehension, and comprehension of distant and secondary semantic relations that are typical for metaphors, idioms, sarcasm, irony, and humor. When the right hemisphere areas supporting these functions are damaged, impairments follow, but they are generally less apparent than those following left hemisphere damage. As a consequence, persons with right hemisphere damage whose language is left lateralized are generally not considered aphasic, even though 50% may have verbal communication difficulties that are socially challenging.

The unique role of the right hemisphere in language remains controversial. For instance, it has been debated whether comprehension of metaphors and other types of figurative language requires support of the right hemisphere. An early behavioral study reported that post-stroke patients with a right hemisphere injury were able to explain metaphoric sentences verbally, but they were correct only half of the time in picture–metaphor matching (Winner and Gardner 1977). An early positron emission tomography (PET) study provided evidence of the role of the right hemisphere in metaphor processing in healthy

adults (Bottini et al. 1994). However, subsequent studies have reported mixed findings, with some indicating that the right hemisphere is involved only in processing less familiar sentential metaphors and others questioning its role in metaphor processing altogether. The discrepancy in findings reported in these studies may be due to the differences in their design, methods, and the populations studied. Regardless, the conflicting evidence illustrates a need for more research on the role of the right hemisphere in language, its contribution to recovery after left hemisphere damage, and its residual abilities after it has been damaged.

Brain Plasticity for Language

Localization of function in the brain is not fixed and the adult human brain retains the potential for changes. This capacity of the brain to reorganize itself structurally and functionally is known as neuroplasticity. Although the concept of neuroplasticity is not new, the potential of the brain to reorganize language function after damage remains relatively unexplored. One general finding is that the extent to which the brain allows functional reorganization after damage depends on the type of lesion: for example, slow-growing lesions, such as low-grade glioma, appear to allow better functional adaption than sudden brain lesions, such as those caused by a stroke (Desmuget et al. 2007).

The most remarkable findings on the potential of the brain to reorganize language function come from studies of low-grade glioma that use intraoperative electrical mapping in awake patients during brain surgery and report patients' performance on language tests at various points in time following tumor resection (e.g., immediately postoperatively, 3–6 months/6–12 months postoperatively). These studies indicate that a language task can be successfully completed even when the brain area that typically supports the task is invaded by tumor or surgically removed. For instance, studies in low-grade glioma patients have shown that removal of the whole left dominant insula (Duffau et al. 2001), Broca's area (Plaza et al. 2009), or Wernicke's area (the posterior two-thirds of the superior temporal gyrus,

middle temporal gyrus, and the supramarginal gyrus) (Sarubbo et al. 2012) did not result in severe language deficits in these respective patients, as would be expected if localization of function in the brain were fixed. To better understand these findings, one must keep in mind that low-grade glioma is a slow-progressing brain tumor with a growth rate of about 5 mm per year (Mandonnet et al. 2003). The relatively slow rate of tumor growth allows a continuous, slow reorganization of functions at risk of impairment. This permits the brain to achieve the level of compensation that appears as (relative) preservation of language function, despite the presence of large tumors in language-related areas and also after their removal.

There are also regional differences in the cortical capacity to reorganize function (Herbet et al. 2016). For instance, the prefrontal cortex, anterior insula, anterior and inferior temporal cortices, and inferior parietal cortex can be compensated for, whereas part of the superior temporal region (including Heschl's gyrus and part of Wernicke's area), the posterior inferior temporal cortex, and the basal ganglia cannot be compensated for. When it comes to white matter, its neuroplastic potential is not as great as the potential of gray matter areas (Herbet et al. 2016). Previous findings in post-stroke aphasia are consistent with this evidence from low-grade glioma, indicating that deep lesions affecting white matter have a worse prognosis than the lesions affecting only cortical gray matter. Finally, while most white matter tracts, including the arcuate fasciculus, cannot be compensated for, portions of some white matter tracts have neuroplastic potential. For instance, the inferior fronto-occipital fasciculus, which is a major ventral white matter tract supporting language, shows a greater plastic potential in its anterior portion than in its mid and posterior portions (Herbet et al. 2016).

On the other hand, developmental data indicate that some language abilities may be compensated for even after damage to the relevant white matter tracts that have a low neuroplastic potential, such as the arcuate fasciculus. For instance, a 15-year old patient who underwent brain surgery for removal of a malignant tumor 10 years earlier

had relatively spared oral language abilities, even with a missing arcuate fasciculus in both hemispheres; however, this patient's reading was completely deficient (Rauschecker et al. 2009). Studies in adults point to a more limited and selective plasticity of the tracts supporting language. A recent study reported that ten patients with low-grade glioma in the left frontal region had normal preoperative language function, but fractional anisotropy values in the left ventral language pathways were increased in these patients compared with healthy control subjects (Zheng et al. 2013). One plausible explanation for the changes in white matter microstructure integrity of the ventral language tracts includes reorganization supporting the patients' normal preoperative language. This interpretation is compatible with the evidence suggesting some degree of regional plasticity of the ventral language tracts (Herbet et al. 2016).

The exciting findings on the brain's potential to reorganize language that come from recent research on low-grade glioma demonstrate what the brain can do, not what it normally does. Nevertheless, these findings are challenging some basic assumptions of the current understanding of language organization in the brain.

Language Deterioration in Dementia

While language disturbances in post-stroke aphasia appear suddenly, language in AD deteriorates slowly and represents a secondary symptom. The main features of cognitive decline in AD, which is one of the most common types of dementia, are impairments in episodic memory, executive functions (reasoning, problem solving, planning), semantic memory, visuospatial skills, attention, and control processes. In addition, language impairments at word-level, such as cued-word generation and confrontation naming, develop relatively early in the disease. At a later stage, word repetition, articulation, and overall production and comprehension become impaired, so that patients in the final stage of the disease experience a profound inability to communicate.

Growing evidence from neurolinguistics suggests that AD patients have a particular difficulty in verb processing (Grossman et al. 2007), which

may be caused not by the semantic content of verbs or limitation of the resources necessary for verb processing, but rather by impaired assignment of thematic roles (Manouilidou et al. 2009). Thematic roles are semantic roles that a verb assigns to a noun to indicate 'who did what to whom' in a sentence. For example, AD patients' comprehension of psychological verbs such as 'fear' or 'frighten' indicates a pattern of spared comprehension of sentences such as 'The boy fears the thunder,' but impaired comprehension of sentences such as 'The thunder frightens the boy.' Findings such as this one escape standard neuropsychological testing of language in AD patients, because it is focused on more general aspects of language.

So far, research on language deterioration in AD has focused on patients who are already at the dementia stage, typically within the range of mild to moderate dementia. However, recently redefined research and diagnostic criteria for AD have promoted a concept of AD as a continuum, including preclinical, prodromal (mild cognitive impairment [MCI]), and dementia stages of AD (Dubois et al. 2010). The new criteria strongly emphasize the role of biomarkers in identifying stages of the disease, such as abnormal levels of cortical amyloid- β and tau-proteins, along with neuroimaging markers of Alzheimer's pathology, such as regional hypometabolism, cortical thinning, gray matter volume reduction, deterioration of white matter microstructure integrity, and changes in networks' connectivity both while performing a cognitive task and while in a resting state. Crucially, specific biomarkers can be mapped to specific stages of the disease.

Neurolinguistic research is lagging behind these important new developments and currently little is known about language deterioration in the initial stages of AD. Evidence so far indicates that MCI patients have deficits in naming and verbal fluency, with some more general speech production and comprehension deficits, as defined in standard neuropsychological test batteries. Moving towards presumably the earliest stage on the AD spectrum – preclinical AD – recent research has suggested that cognitively normal persons harboring Alzheimer's

pathology, such as increased levels of cortical amyloid- β , show considerable changes in network activation related to cue-based word retrieval in comparison with cognitively healthy persons who do not harbor Alzheimer's pathology (Papp et al. 2016). In other words, even though symptoms of language decline are still not manifest at the preclinical stage, the network changes related to the task performance are already present. One methodological problem with current research on language in preclinical AD is related to the type of language tests used. They typically include verbal fluency, naming, etc. from standard neuropsychological batteries, even though such tests are more appropriate for advanced stages of the disease and miss subtle changes. Thus, to advance understanding of language abilities in early AD, research needs to move beyond standard neuropsychological tests and investigate more specific linguistic hypotheses on various aspects of language representations and computations.

Finally, an important topic related to language and AD pertains to the role of bilingualism in cognitive and brain reserves in persons with Alzheimer's pathology. Some evidence indicates that active use of two (or more) languages on a regular basis contributes to cognitive (and brain) reserve and delays the onset of dementia by 4 years (Bialystok et al. 2007). The idea is that regularly switching between two languages strengthens executive control functions, which deteriorate early in AD. A recent study reported that monolingual persons were diagnosed with AD 5 years earlier than those who were bilingual, 6.4 years earlier than those who were trilingual, and 9.5 years earlier than those speaking four or more languages (Freedman et al. 2014). Still, methodologically more desirable longitudinal studies on the topic are scarce and some report lack of evidence for the protective effect of bilingualism on the onset of AD symptoms (Zahodne et al. 2014).

Does Language Decline with Aging in Cognitively Healthy Persons?

Some research on cognitive aging indicates that language declines in cognitively healthy elderly

persons. Examples of language decline include reduced vocabulary, production of sentences with a smaller mean number of clauses per utterance, and difficulties with grammaticality judgments and comprehension of complex syntax. Other evidence supports the view that cognitively healthy elderly persons have largely preserved language abilities, including syntax, but that they appear to experience difficulties with word retrieval. As an example, in tip-of-the-tongue states, the meaning of a word is available but word form remains elusive, so that the person in this state is left with the impression that the word is 'on the tip of the tongue' and yet they cannot retrieve it from the mental lexicon. According to one model, word retrieval difficulties in cognitively normal elderly persons are caused by impaired phonological access. However, there is no persuasive neurobiological argument to postulate this exact type of word retrieval difficulty in cognitively intact elderly persons.

On the other hand, word retrieval deficit is typical in a range of neurological conditions, including MCI and AD dementia. Recent findings indicate that Alzheimer's pathology is far more frequent among cognitively healthy elderly persons than previously recognized (Jack et al. 2014). Besides, until recently it was not possible to study in vivo brain changes associated with Alzheimer's pathology (e.g., increased cortical levels of amyloid- β tau-proteins). Thus, previous research on word retrieval in normal cognitive aging could not differentiate between cognitively normal elderly persons with Alzheimer's pathology and cognitively normal elderly persons without this specific pathology. It is therefore possible that previous findings that suggested impaired phonological access in 'cognitively normal' aging actually pertain to a mix of persons who are healthy and those harboring Alzheimer's pathology, i.e., preclinical AD (Kljajevic 2015). Future studies on language in healthy cognitive aging need to define more precisely the exclusion criteria regarding neuropathology in elderly persons in order to avoid mixing cognitively intact and preclinical AD populations.

Conclusion

Language dysfunction may result from brain injury, as in stroke and trauma, or from a progressive disease, as in brain tumors and neurodegenerative diseases. It appears that the brain can adapt to such changes to some extent, supporting the concept of functional compensation. However, overcoming specific patterns of language disturbances depends on multiple factors and in many cases it may not be possible.

Definition

A 1994 book by Steven Pinker.

Introduction

The Language Instinct is a [1994](#) book by Canadian-born cognitive scientist and linguist Steven Pinker (born September 18, 1954). In it, Pinker asserts that the human capacity for language acquisition is innate. In many ways, Pinker agrees with Noam Chomsky's theory of universal grammar, which states that language is hard-wired in the brain; that language skills develop naturally without instruction, rewards, or punishments; and that properties shared by all human languages demonstrate that it is a universal human trait. He does, however, consider himself more credulous than Chomsky regarding the ability of the theory of evolution by natural selection to explain our innate language capacities.

Refuting Misconceptions About Language

Pinker illustrates that children learn a great deal about language without instruction, which he claims is at odds with common conceptions of language learning. In addition, he criticizes common assertions that the typical person has poor grammar and that language is degenerating over time. He also provides evidence against certain

academic linguistic theories such as the Whorfian hypothesis (also known as linguistic relativity), which states that the properties of a specific language affect how its speakers can perceive and talk about the world. He is especially critical of the “strong version” of this hypothesis: that language determines thought. For instance, one could claim, based on the strong version of the Whorfian Hypothesis, that a speaker whose native language has no word for “rebellion” would be unable to express or perhaps even have thoughts of rebellion. Pinker argues in *The Language Instinct* that thought is independent of language and asserts “the more you examine Whorf’s arguments, the less sense they make” (p. 60).

Innateness of Language

Pinker views language as unique to humans and as an ability that allowed our ancestors to adapt to selection pressures whereby hunter-gatherers who could more effectively communicate with each other would have a survival advantage over those who could not. And because language capacity evolved as the result of a domain-specific selection pressure, Pinker asserts that it is a unique mental module rather than a component of a more domain-general skill such as general cognitive ability. Research supports such a view by demonstrating a double dissociation between brain injuries resulting in loss of language abilities and those resulting in loss of general cognitive ability (e.g., Dunn and Kirsner 2003). For example, a condition known as specific language impairment results in impairment of language skills without impairment of cognitive ability (van der Lely 2005), and a condition known as Williams syndrome results in impairment of cognitive abilities but not a direct impairment of language (e.g., Bellugi et al. 1988).

The Universal Sequence

That language is a product of natural selection and an innate part of human nature means that is not the direct product of human culture; it is not a

human invention in the same way as the wheel or the computer. Language is universal across all human cultures, whereas human inventions are not. Pinker asserts that the universal sequence of language acquisition – wherein children first demonstrate language through babbling, then holophrases (single words expressing an entire thought), and other intermediate stages before achieving mature language skills – is apparent even in deaf individuals. He cites research evidence of “manual babbling” (babbling with hand gestures) in deaf infants (e.g., Petitto and Marentette 1991).

Critical Periods

Additionally, Pinker points to so-called critical periods in language development (age ranges during which a child must have a certain experience in order for language skills to develop normally) such as those detailed by Kuhl et al. (2003). Such specialized and rapid learning processes are not explainable by operant conditioning or formal instruction.

Pinker claims that these findings as well as the natural development and acquisition of language skills in the absence of formal instruction are indicative of the innateness of spoken language.

Definition

The notion that human cognitive architecture includes a module for language, i.e., an innate system of neural tissue that responds only to speech.

Introduction

The concept of a modularized mind, constructed of distinct units devoted to particular psychological functions, can be traced back at least to Gall, the father of the nineteenth-century phrenology. In the twentieth century, a version of modularity (termed “the new organology” by detractors) was advocated by Chomsky, who speculated that some sort of language module would be necessary to support his universal grammar (e.g., Chomsky

1980). Today modularity is most closely identified with Jerry Fodor, whose publication in 1983 of *The Modularity of Mind: An Essay on Faculty Psychology* (Fodor 1983) electrified the still-young field of cognitive psychology. Fodor’s modularity, which depicts modules as hardwired information processing systems, appealed to a generation of psychologists who were intent on peering into the behaviorists’ “black box” of the mind and were hungry for technical language to describe what they had begun to find there. The theory’s impact on the cognitive and language sciences has been broad, deep, and enduring.

Fodor’s Modularity of Mind

The idea of a modular mind emerged from Fodor’s philosophical view of the brain as a computer. Fodor argues that innate cognitive modules, or “input systems,” are necessary to interpret information encountered “at the surfaces (as it were) of the organism” (Fodor 1983, p. 42) such that it is comprehensible by the “central systems” of the brain, where conscious, higher-order cognitive processes occur. Although he sidesteps providing a detailed list of candidate modules, Fodor does grant that there are likely to be modules for at least “the perceptual systems *plus language*” (emphasis original; Fodor 1983, p. 44). He argues that a module for language interpretation is as valuable to humanity as a module for perception of light or odor on the grounds that all of these hypothesized input systems serve the function of generating hypotheses about “the way that the world is” (p. 45) for use by higher-order cognitive systems. Processing the speech of others, Fodor points out, is a generally reliable way of obtaining information about the world – “In the root case, the convention is that we say of *x* that it is *F* only if *x* is *F*” (p. 45) – and thus a module for speech processing is adaptive.

In *Modularity of Mind*, Fodor provides nine criteria that he concludes are useful in identifying a module, two of which have received outsized attention by both supporters and critics of his thesis: *domain specificity* and *informational encapsulation*. Modules are domain specific in

that they respond only to a particular stimulus domain, for example, the purported language module responds to speech, but not to nonspeech auditory stimuli. Modules are informationally encapsulated in that they are autonomous, i.e., they do not interact with central systems or with each other. The primary implication of encapsulation for the language module is that prior knowledge or beliefs – that is, top-down information flow – will not interfere with speech perception. Fodor dismisses evidence of top-down influences on language comprehension, such as the ability to understand acoustically degraded speech, or the phoneme-restoration effect, as post-perceptual (in the case of the former) or as intramodular flow (in the case of the latter).

The modularity thesis has become unfashionable among cognitive psychologists in recent years (“I am well aware of efforts to debunk this view, the arguments raised toward that end, and the disfavor into which a modular view of the mind has fallen,” comments Curtiss (2013, p. 90) in a recent defense of modularity), for a number of reasons. For one, the double dissociations between language skill and general cognitive abilities in lesion patients and individuals with genetic syndromes that are predicted by a language module segregated from other neural tissue have proved elusive (e.g., Stojanovik 2014; although see Barrett and Kurzban 2006, for an account of the unlikelihood of finding perfect dissociations even in a completely modular system). Additionally, advances in neuroimaging in the past 20 years have failed to reveal spatially or connectively “encapsulated” tissue for language or, for that matter, anything else.

Finally, the concept of “computer” has changed considerably since the publication of *Modularity of Mind*. In the past 30 years, connectionist networks that reliably simulate many aspects of cognition by exploiting parallel distributed processing and spreading activation of information have largely eclipsed the serial, symbol-reading devices on which Fodor modeled his view of the mind. If alternative models of the computer had been available in the 1970s and

early 1980s, Fodor could have perhaps conceived of a different architecture of the mind that is nonetheless computational (cf. Katz 2014).

Reconceptualizing Modularity

However, the modularity thesis might remain viable if one is willing to accept a looser definition of a module. The encapsulation requirement now seems fairly untenable, but the same is not necessarily true of the domain-specificity requirement. It is well established that there are certain areas of the brain, and networks of these areas, that are reliably involved in language processing (e.g., Fedorenko 2014). Thus, cognitive psychologists and neuroscientists almost universally allow that there is functional specialization for language. (The terms “domain specific” and “functionally specialized” are used interchangeably here, although others have differentiated them.)

Of those who are willing to declare the language network a module, its provenance is still a matter of serious contention. A spectrum of thinking on the matter stretches from strong nativism on one end to complete emergentism on the other. Nativists such as Curtiss, whose doctoral dissertation examined the famed case of Genie, point to differential activation patterns in response to speech versus other acoustic stimuli in the brains of infants as evidence that neural speech systems are hardwired (Curtiss 2013). Emergentists, meanwhile, are highly dismissive of the notion that a “blueprint” of the mental structures that will develop in an individual is genetically programmed. Karmiloff-Smith (1992) argues that modules are formed wholly through interactions with the environment, and Barrett and Kurzban (2006) provide an evolutionary mechanism for their emergence: natural selection has provided humans with genes that allow the brain to functionally specialize in response to stimuli and environments that have been reliably encountered across human history. It follows that “if the normal environment of development is changed, developmental outcomes might be different” (Barrett and Kurzban 2006, p. 638).

Thus, for the nativist, Genie's brain was denied the linguistic input required at the right moment in development to rouse its innate language module; for the emergentist, because Genie was denied linguistic input at the right moment in development, the gene-by-environment calculus that causes the language module to emerge under normal circumstances was disrupted, and no such module ever formed. Yet another view departs from the nativist-emergentist spectrum altogether, and has languages evolving to fit brains, rather than the other way around (Christiansen and Chater 2008). This view puts any biological adaptation for language as recent, minimal, and falling far short of anything that could be considered a module, even in a relaxed sense of the term.

Conclusion

Despite the increasing skepticism with which the modularity thesis has been viewed in certain academic circles in the past two decades, it is by no means obsolete. It is a touchstone for many evolutionary psychologists, who feel that Fodor was in fact too conservative when he denied modularity to the central systems of the brain. They posit instead that the brain is massively modular, because a large number of functionally specialized cognitive systems should be more flexible in the face of a changing environment than a small number of functionally general systems (e.g., Tooby and Cosmides 1992; Barrett and Kurzban 2006).

When *Modularity of Mind* was first published, one might have assumed that the invention of a noninvasive technology for watching a brain in action would go a long way toward settling the question of the validity of Fodor's theory. Today, nearly 25 years after functional magnetic resonance imaging was first used to watch human brains at work, the debate is far from settled. Modern conceptualizations of modularity are strongly altered from the one Fodor proposed, but the usefulness of the construct for framing central questions in the study of human cognition has ensured its survival to the present day.

Genus that encompasses modern and extinct human species

Introduction

The brain and cognition have been studied from an evolutionary perspective for many years with size often correlated with aptitude. Still we have seen from animal models that brain size does not always predict ability. For humans, our greatest adaptation has been the development and efficiency of our brains, which many would define as a consequence of their relative size. Therefore to better understand the evolutionary psychology of human development, exploring the largest brain in our genus would be paramount.

Variations of *Homo*

To be classified as a species of the genus *Homo*, the following features – a mean cranial capacity greater than that of members of the genus *Australopithecus*, muscular ridges on the cranium, smaller features such as the mandible and maxillae, and distinct differentiation in bone structures – must be present (Antón and Snodgrass 2012). Within the genus exists the *Homo habilis*, *Homo erectus*, *Homo neanderthalensis*, and *Homo sapiens*. The *Homo habilis* are the most ancient representative of the genus *Homo*. They inhabited parts of the world, roughly two million years ago. *Homo sapiens* are the only surviving species of the genus *Homo*, as well as the only extant human species.

From various gatherings of information known to date, scientists have deemed *Homo sapiens* as the most intelligent species of the genus. Research on intelligence has stated that a relationship exists with anatomical structures, such as brain size and capacity. Neanderthals were known to have larger brains than *Homo sapiens*; however compared to body mass, Neanderthals actually had smaller brains than modern-day *Homo sapiens*.

Consequently, brain sizes, specifically in *Homo sapiens*, were and continue to be researched throughout the years. Several factors have been attributed to increased brain structures. Currently, *Homo sapiens*' brains weigh roughly 1,400 g and are around three times the size of the brains of great apes. It is also larger than presumed for the size of the human body. Fossil evidence of the direct capacity of the cranial size has been linked to the hominin evolution, with increased growth in size over the past two million years. In comparison to the other species, chimpanzees and bonobos have similar brain structures but differ significantly in social skills and behavior (Verendeev and Sherwood 2017).

What Influences Brain Size?

The differences surrounding brain structures and features have led researchers, such as Healy and Rowe (2006), to find that behavioral ecologists

are interested in the ecological factors and life history traits that may be associated with brain size. Through the investigation of these factors, ecologists' research focused on identifying the most important selection pressures. Over the past 10 years, analyses comparing brain size and its evolution have been conducted. Some recent studies have found a relationship between the brain's size and behavioral traits such as migration, deception, and female promiscuity (Healy and Rowe 2006).

In contrast, other studies have explained that there may be a dietary association with the growth in the brain size of mammals. In other times, diet appeared to explain the brain's formation and size in nonhuman primates. Among many other evolutionary researchers, Foley and Lee (1991) have agreed that the variation in the brain structure's size could be attributed to ecological factors, such as life history parameters. A conclusion drawn from the research is that "large brains resulted from various increases in size of parts of the brain, according to their importance" (Mace et al. 1980). Additionally, differences in brain areas could synchronously occur, causing trade-offs between the areas that cannot be measured as whole brain size. Therefore, although brain size was attributed to corresponding ecological factors, it has also been linked to increased function.

From an evolutionary standpoint, these changes in brain size have been linked to many different hypotheses. Among these, the three major theories have focused on the demands of ecology, climate change, and social competition.

Climate change is considered one of the major theories that could explain the increase in brain size, due to the unpredictable changes in the weather. As many ice ages occurred throughout the earth, these unpredictable weather changes accompanied them. As a result, many of our ancestors migrated away from the equator and encountered challenges, such as a depletion of resources. The scarcity of resources led to the development of greater skills used for survival. Among these skills, their ability to find resources and in turn "cleverness" may have resulted in the expansion of their brain capacity. In addition, the climate shifts that caused the migrations to the

north or south of the equator could have further influenced the exposure to the parasites found in the surrounding environments. Because there are fewer parasites found as you migrate further away from the equator, it could be presumed that *Homo sapiens* were not consuming their energy and calories to fight off pathogens, thus allowing for these calories and energy to be used to further influence brain development.

A more commonly known hypothesis is that of social competition for resources which influenced brain size. As aforementioned, the scarcity of resources led to the development of greater skills used for survival due to the competition for resources. As the population grew, the number of individuals contesting for the same resources grew as well. This hypothesis is rooted in the idea that those of higher social status in an environment would have more access to resources, leading to their offspring having higher chances of survival. Those that are not considered as socially adept will eventually die off and consequently influence the group as a whole, by increasing their social "fitness." According to this evolutionary hypothesis, the effects of the social competition could cause the increase in brain size.

In a study conducted in March 2009, 175 skull fossils from humans and other species of the genus *Homo* were studied. Many variables, such as how old the fossils were, the temperature of the environment in which the *Homo* species lived, where they were found, population density, and level of parasites in the environment, were studied (Bailey and Geary 2009). The variables were used in a statistical analysis which concluded that the best predictor of the increase in the *Homo* brain size is population density. This variable further explains the social competition between species since a higher population density would indicate that there is a larger population in an environment. The results of this study also showed that the climate changes contributed to the developments in the *Homo* brain, but were not as significant as the variable of population density. Although the social competition hypothesis seems to be the best explanation for the growth of the *Homo* brain, there is no concrete evidence that certain species,

such as the *Homo erectus*, were in fact in social competition.

Brain Size and Intelligence

The changes in brain size may be linked to differences in the brain development, neuroanatomical reorganization, and modifications at the molecular level (Healy and Rowe 2006). Further studies suggest that the increase in brain size is uniform, as a result of the rate and cessation of symmetrical cell cycles being identical. If differences in cell cycles are among regions of the brain, the result would be a “positive or negative allometric growth” (Roth and Dicke 2005). This kind of growth within the brain has been classified as a source of increase in function; this may be a result of the difference in intelligence levels.

It is probable that the reorganization at certain molecular levels, and not solely the brain size and capacity, produces the distinction in cognition among various species. The increase in human brain size is due mostly to the expansion of the neocortex, specifically heteromodal association regions of the temporal, parietal, and frontal lobes. These evolutionary changes to human association cortex involve the enlargement of structures that “are homologous in other primates and alterations to cortical connectivity” (Verendeev and Sherwood 2017). This rapid growth has been linked to the base of certain genetic mechanisms. As explained by researchers, these mechanisms resulted in a cell division process that has contributed to the expansion of the cranial capacity (Roth and Dicke 2005).

However, some researchers, such as Rogers (2004), do not support that the association between brain and behavior could be explained solely by measuring whole brain size. They believe that the brain must be studied in separate components such as specific brain regions that have changed evolutionarily to allow for advanced functioning. Among these specific regions, the evolution of the cerebral cortex and cerebellum suggests an increase in cognitive and affective functioning among *Homo sapiens*.

As aforementioned, humans are known to be the most intelligent species among animals.

Compared to other mammalian brains, the human brain has been viewed as the most cognitively able, with an overdeveloped cerebral cortex that represents over 80% of the brain mass, with 100 billion neurons (Herculano-Houzel 2009). It is unclear which exact characteristics of the brain determine the difference in intelligence levels among animals. However, studies have found that the following properties – theory of mind, imitation, or a syntactical language – may not be uniquely found in humans, challenging the notion that human beings are the most intelligent species. Other studies have conveyed that controversy has existed among the topic of larger brain capacity associated with greater intelligence due to research that has found that some animals with smaller brain capacities do have higher brain functioning (Herculano-Houzel 2009).

The findings of many research studies have demonstrated that the human brain resulted from the changes in evolution that occurred progressively and explain their advanced cognitive functioning. In contrast to Herculano-Houzel (2009), noting the controversy that exists in explaining intelligence levels in correlation with brain size, Verendeev and Sherwood (2017) discussed the relative size and additional cortical areas that most likely contributed to an advanced neuroanatomical basis for “fine-grained information” and higher levels of processing among *Homo sapiens*. Among these anatomical changes exist the changes evident in microstructure, such as the distribution patterns of neurons and glial cells, which allowed for plasticity and increased learning capacity. These anatomical changes, in combination with cultural and social forces, helped shape human cognition to develop to what it is today (Verendeev and Sherwood 2017).

Although the structure of the human brain continues to be studied and discussed in correspondence to ability and function, other components have been correlated with increased brain size. For example, diet has played a role in increased brain size. A study by Navarette et al. (2011) challenged the “expensive-tissue hypothesis” which claims that the evolutionary changes within the brain are correlated to the evolutionary differences in the digestive tract (Navarette et al. 2011). The hypothesis has been widely supported by

many researchers and scientists but has shown little empirical support. It was found that controlling for fat-free body mass, the brain size is not negatively associated with the mass of the digestive tract or any other organ, refuting the expensive-tissue hypothesis (Navarrete et al. 2011). The notion that early species of the genus *Homo* evolved larger brains due to dietary changes, such as more meat and cooked food, leads to the idea that this allowed for a smaller digestive tract. As a result, the large brains found in *Homo sapiens* have been suggested to act as cognitive buffers against starvation, thus reinforcing the idea that nutrition and diet may have indeed contributed to the evolution of a larger brain capacity.

Conclusion

In conclusion, it is difficult to distinguish the exact properties that contributed to the large brain size of *Homo sapiens*. As mentioned across studies, the combination of neuroanatomical growth, diet, and social function may be attributed to the advanced function of the human mind, such as theory of mind and complex cognitive ability. However, it remains unclear whether an association between the whole brain size or certain brain properties and levels of intelligence directly exists. There is also minimal concrete evidence that supports the evolutionary theories of social competition and climate change to be the ultimate predictors of the increase in brain size. Therefore, additional research on the *Homo* brain and its growth in capacity should be facilitated to further understand the rapid changes which may promote future brain size development.

Laryngeal Descent

W. Tecumseh Fitch
Department of Cognitive Biology, University of
Vienna, Vienna, Austria

Synonyms

Descended larynx, Descent of the larynx, Vocal tract reconfiguration

Definition

Laryngeal descent refers to a movement of the larynx away from the oral and nasal cavities in humans or other mammals, either temporarily during vocalization (dynamic descent) or permanently during development (permanent descent).

Introduction

It has been known since the nineteenth century that adult humans are unusual in having a descended larynx. In most mammals, the resting position of the larynx is directly beneath the palate, at the back of the oral cavity, and the epiglottis (a flap of cartilage at the top of the larynx) can be inserted into the nasal passage to form a sealed respiratory passage from the nostrils to the lungs. In humans, in contrast, the larynx descends away from the palate during infancy, and adults can no longer engage the larynx into the nasal passages. This trait was once thought to be unique to humans and to play a central role in our ability to speak, but it is now known that most mammals dynamically lower the larynx during vocalization and in addition that many species have a permanently descended larynx comparable to that in humans. There is thus little indication that a descended larynx plays a crucial role in human speech control or language capabilities.

History

For many years, the descended larynx was believed to be unique to humans, supporting the inference that it was crucially involved in speech production (Lieberman 1968, 1984). Because descent of the larynx in humans also pulls the tongue base, supported by the basihyoid bone, down away from the palate, it leads to a reconfiguration of the vocal tract geometry, with an oral and pharyngeal cavity of roughly equal length and volume. Moving the tongue around within this reconfigured vocal tract allows adult humans to produce extreme vowels that would otherwise not be possible. Particularly when a

descended larynx was thought to be unique, this was thought to be closely associated with the evolution of spoken language.

In 2001, researchers studying deer vocalization discovered that adult males of two European deer species – red deer *Cervus elaphus* and fallow deer *Dama dama* – have permanently descended larynges, with a resting location comparable to adult humans, roughly halfway down the neck (Fitch and Reby 2001). Once alerted to this possibility, researchers have now found comparable permanently descended larynges in many other species, including tigers, lions, jaguars, koalas, and Mongolian gazelles (reviewed in Fitch 2010)

Furthermore, by using x-ray video to observe the vocal tract of living animals while they vocalized, it was found that a *dynamically* descended larynx is observed during at least some types of calls in all mammals yet studied (Fitch 2000), indicating that vocal tract geometry is in fact highly flexible and that any mammal is capable of reconfiguring its vocal tract during vocalization. These new observations clearly indicate that neither a dynamically nor a permanently descended larynx is uniquely human.

Development

Human newborns have a vocal tract configuration like that of most other species, with a high larynx that can be inserted in the nasal cavity but can be retracted during crying. However, starting around the age of 3 months, the larynx begins to retract away from this position, reaching an adult-like geometry by around 6–8 years of age (Lieberman et al. 2001; Sasaki et al. 1977). The mechanical forces that lead to this descent are not known. However, recent data indicate that a similar, though less extreme, extent is seen during chimpanzee development (Nishimura et al. 2006).

It is also well known that a second descent of the human larynx occurs during puberty but only in males (Lieberman et al. 2001). This leads to a sexual dimorphism between adult men and women in vocal tract length, with men having significantly longer vocal tracts, which gives men lower formant frequencies. This vocal tract

elongation is physiologically and acoustically independent of the growth of the larynx itself which, by lengthening the vocal folds, is responsible for men having lower-pitched voices than women. However, both of these changes occur during puberty.

Adaptive Function

When the descended larynx was believed to be unique to humans, only one hypothesis for its adaptive function seemed plausible: the idea that it served to increase the discriminability of speech sounds and thus to improve speech communication (Lieberman 1968, 1984). This led many researchers to assume that the permanent descent of the larynx played a crucial role in the evolution of spoken language. The newer comparative data have called this assumption into question. First, dynamic descent of the larynx allows all mammals to reconfigure their vocal tract by elongating the pharynx, and in some species (such as dogs) this reaches human-like proportions (roughly equal oral and pharyngeal cavities). This suggests that, for any species or at any point in hominin evolution, the vocal tract could be dynamically reconfigured to enlarge the range of producible speech sounds.

The most plausible function of the dynamic descent of the larynx seen in dogs, pigs, monkeys, and other mammals is that it allows vocalizations to be produced through the oral cavity rather than the nasal cavity. Because the nasal cavity, with its conchae and increased surface area, absorbs acoustic energy, orally produced vocalizations will be louder than nasally emitted sounds. Consistent with this, quiet close-contact vocalizations (such as grunts in pigs or whines in dogs) appear to be nasally emitted, and it is only loud vocalizations (pigs' squeals or dogs' barks) that are produced orally with a descended larynx. This hypothesis also explains why human infants lower their larynx during crying.

Regarding permanent descent, those non-human mammals who exhibit a permanent descent of the larynx use it to produce loud

and impressive display vocalizations like roars and do not appear to use it to produce a wide variety of vowel-like sounds (and obviously, deer, lions, and koalas do not speak). Rather, current data supports the idea that laryngeal descent and the concomitant elongation of the vocal tract are an adaptation to make the vocalizer sound larger than it otherwise would. Formants are known to be correlated with body size in many (probably most) mammals, and thus can provide an important cue to body size (Pisanski et al. 2014; Reby et al. 2005). By elongating its vocal tract while vocalizing, an animal can thus match the acoustic properties of a larger animal, exaggerating its own apparent size.

This size exaggeration hypothesis (Fitch and Reby 2001) now has ample support in nonhuman species. But what of humans? The later descent of the human larynx occurs during puberty only in men, and men do not have superior speech abilities to women (if anything the contrary is true). Thus, it is unlikely that this pubertal male descent has to do with improving speech sound discriminability. Rather, it is most likely that this pubertal descent also serves to exaggerate the impression of body size conveyed by male voices.

Conclusion

Although long thought to play an important and unique role in human speech, it is now clear that a descended larynx is phylogenetically widespread among mammals and appears to fulfill multiple adaptive functions. Because most mammals appear to have flexible vocal tracts, a capacity for laryngeal descent is a typical mammalian trait. This means that, were a human brain in control, a monkey or dog's vocal tract would be perfectly capable of producing a wide range of discriminable speech sounds, fully adequate for linguistic communication. Thus, a permanent descent of the larynx was not an important hurdle that human ancestors needed to cross in order for spoken language to be possible. Regarding the permanently descended larynx, the size

exaggeration hypothesis provides the most plausible explanation in those nonhuman mammals that exhibit this trait as well as in adult human males. What remains more difficult to understand is why the larynx descends during infancy, in both males and females. The fact that this occurs in both chimpanzees and humans suggests that this early descent was already present in the common ancestor of humans and chimpanzees and thus that this too serves some nonspeech function, perhaps allowing young animals to produce louder vocalizations.

In conclusion, the widespread idea that the human descended larynx is or was a crucial adaptation for speech is not supported by the comparative data. This also implies that attempts to date the emergence of language by using fossils to determine laryngeal position is misguided. Although a permanently descended larynx probably does allow humans to produce a slightly larger vowel space, with a greater degree of control than would be possible with the dynamic descent seen in dogs or monkeys, the comparative data suggest that this is a matter of degree and not a difference in kind, and in fact may be a by-product of other selective forces (e.g., increasing loudness or size exaggeration by formant lowering).

Synonyms

[Last male precedence](#)

Definition

The preference for females to be fertilized by the last male they engaged in coitus with. Some species possess first male precedence, the preference for females to be fertilized by the first male they engaged in coitus with.

Introduction

Last male advantage is one example of what some researchers call “sperm precedence,” “sperm predominance,” or “ordinal ejaculation effects.” It is the phenomenon of females being more likely to be fertilized by the last male they engaged in coitus with. While some species possess “first male advantage” or “precedence” (the preference for females to be fertilized by the first male they engaged in coitus with), humans possess a pattern of last male precedence. This is believed to be a result of the semen displacement hypothesis (see ► [“Genital Evolution”](#)).

The semen displacement hypothesis posits that the human penis, with a relatively larger glans and more pronounced coronal ridge than is found in many other primates, may function to displace seminal fluid from other males in the vagina by forcing it back over/under the glans. During intercourse the effect of repeated thrusting would be to draw out and displace foreign semen away from the cervix. As a consequence, if a female copulated with more than one male within a short period of time, this would allow subsequent males to “scoop out” semen deposited by others before ejaculating (Baker and Bellis 1995).

To test this hypothesis, Gallup et al. (2003) used artificial models and measured the magnitude of artificial semen displacement as a function of penile morphology, depth of thrusting, and semen viscosity. The magnitude of displacement was directly proportional to the depth of thrusting and inversely proportional to semen viscosity. The researchers identified the coronal ridge and frenulum as key morphological features in semen displacement. Gallup et al. (2003) also found that males appear to modify the use of their penis in ways that are consistent with the

displacement hypothesis. Sexually active males and females reported deeper and more vigorous thrusting when in-pair sex occurred under conditions related to an increased likelihood of female infidelity.

According to the semen displacement hypothesis, we would expect sperm competition among humans to involve ordinal ejaculation effects. Under conditions in which several males copulate with a female in close temporal proximity to one another, the male who mated with the female last would have an advantage. The last male in the sequence would be in a position to displace the semen left by previous males before inseminating the female with his own semen. This assumes, of course, that other factors such as sperm quality, ejaculate size, penis length, and female control of mating are constant (Baker and Bellis 1995).

Last male advantage is found in several other species, including the honeybee, damselfly, fruit fly, bush cricket, dragonfly, water bug, various beetles, spiders, crabs, finches, butterflies, and other species (see Smith 2012, for a review). In several species, including fruit flies, moths, and damselflies, this effect is clearly due to semen displacement.

This last male advantage would be the major driving factor in the evolution of penile morphology discussed above. This has been well documented in rodent and insect species. Penises in various species have specific features: spines, barbs, spicules, or huge coronal ridges, that function to remove previously deposited sperm or copulatory plugs left by previous males. The type of penile morphology corresponds to the type of copulatory plug the species possesses, with harder spicules or spines for harder copulatory plugs. In the rat, the importance of striated penile muscles has been emphasized (Baker and Bellis 1995).

Conclusion

Many species show a reproductive advantage to being the last male to mate with a female, and the evolution of male genitalia plays a pivotal role in this phenomenon.

Lateral Geniculate Nucleus

Alexander Maier¹ and Michael C. Schmid²

¹Vanderbilt University, Nashville, TN, USA

²Newcastle University, Newcastle upon Tyne, UK

Definition

The lateral geniculate nucleus (LGN) is a small section of the dorsal thalamus. It relays visual information from the retina to visual cortex.

Synonyms

[Lateral geniculate complex](#)

Introduction

The LGN derives its name from its characteristic curved shape resembling a bent knee (*lat.* “genu” for knee). While the medial geniculate is part of the auditory pathway, the lateral geniculate is concerned with vision. Its primary function is to relay sensory information from the retina to the visual cortex via a large fiber bundle called the optic radiation.

Basic Anatomical Organization

In all mammalian species, the outputs of the two eyes in the form of retinal ganglion cell projections (i.e., the optic nerve) terminate at the LGN of the thalamus (see Jones (2007) for a comprehensive, comparative description of thalamic organization). Both the inputs to and structure of the LGN differ across species. For example, only one third of all retinal output projects to the LGN in rodents, whereas 90% of all retinal output projects to this structure in primates, suggesting a more central role for vision in primates. Across all mammals, LGN neurons primarily project to visual cortex, rendering the LGN a relay between the eye and the cerebral cortex. The LGN is often separated into several layers of similar cell types reflecting ganglion cell-specific input. LGN organization varies across species, with the most prominent lamination present in primates and visually engaged carnivores, such as the cat. The LGN of these species constitutes several cell-rich layers that alternate with comparatively cell-poor interlaminar zones. For example, the LGN of macaque monkeys, arguably the best-studied species with respect to visual function, consists of six distinct cell-rich layers and intralaminar zones, constituting three separate projection systems that each reflects specific aspects of retinal output (Fig. 1). Each LGN layer receives input from one of the two eyes, resulting in a pattern of alternating inputs from each eye across LGN layers, although this patterning is less apparent in some species. In macaques, layers 1, 3, and 6 receive input from the contralateral eye (i.e., the eye that sits on the other side of the skull), and layers 2, 4, and 5 are innervated

Lateral Geniculate Nucleus, Fig. 1

Schematic representation of the retino-geniculate pathway to V1.

Microscopic picture shows LGN's laminar organization

by the ipsilateral eye (i.e., the eye that sits on the same side of the skull). In addition to retinal input, some neurons in the most ventral part of the LGN also receive input from the superficial layers of the superior colliculus, a midbrain structure that also receives direct retinal projections. Although about one third of LGN neurons are local interneurons providing inhibitory input to LGN projection neurons, the main inhibitory input to the LGN is from neurons of the neighboring thalamic reticular nucleus. LGN cell types display different immunoreactive sensitivity, which can be exploited by cell type-specific genetic targeting and immunohistochemical labeling.

Three Parallel Cortical Projection Systems

In primates, the three main LGN projection systems consist of big (magno), small (parvo), and very small and sparse (konio) cell types located in layers 1 and 2 (magno), 3–6 (parvo), and interdigitated layers (konio) (described in detail in Usrey and Alitto (2015)). The magno and konio systems each constitute 10% of primate LGN relay neurons, and parvo neurons constitute 80%. The three

projection systems remain segregated on their path from retina to visual cortex. This is reflected in their distinct retinal inputs consisting of parasol, midget, and small bistratified retinal ganglion cells feeding LGN magno, parvo, and konio neurons, respectively. The segregation into three distinct LGN streams is maintained for the projection to primary visual cortex (V1) but appears to break apart for subsequent cortical processing, where these signals appear more intermixed. The main V1 targets for LGN projections are the granular layers 4A and 4Cb for parvo, 4Ca for magno, and layers 2 and 3 for konio projection neurons, respectively. However, there are also sparser projections to deep cortical layers. A distinct feature of the konio system is that at least part of its ascending projections bypass V1 entirely and project directly to higher cortical areas, mediating residual vision following V1 injury (► “Blindsight”).

Functional Organization

Visual functions of the LGN are described in detail in Hendry and Reid (2000) and Jones (2007). LGN neurons typically receive convergent input from 1–5 retinal ganglion cells, with a

smaller number for the fovea compared to the periphery. Neighboring LGN cells receive inputs from neighboring groups of retinal ganglion cells, resulting in a two-dimensional topography termed “retinotopy.” Electrophysiological measurements of LGN neuron response properties to various types of visual stimuli largely confirm this neuronal convergence. LGN neurons are optimally excited by visual (light) stimulation of a small patch of the retina termed the receptive field. LGN neurons’ responses closely resemble the response properties of retinal ganglion cells in that they either respond to the onset or the offset of light (ON/OFF cells). The strongest LGN responses are evoked if a small bright or dark stimulus is surrounded by the inverse pattern of visual stimulation. The so-called ON cells respond best if the center of their receptive field is stimulated by a patch of light while the surrounding region of visual space resides in the dark. In the same vein, OFF cells respond best if a dark patch is placed into the center of the receptive field while there is light in the surround. Across species, most LGN cells receive inputs from one eye only. However, in rodents some LGN cells are innervated by retinal ganglion cells of both eyes, suggesting that neurons in rodent LGN encode inputs to both eyes. Binocular LGN responses have also been shown for the cat. In this species, the activity of the majority of LGN neurons is different when both eyes are stimulated than when just the eye that provides the main excitatory drive is stimulated. In contrast, most neurons in monkey LGN are sensitive to one eye only, suggesting that activity relating to the two eyes is separated before primary visual cortex. In primates, the most characteristic feature of parvo neurons is their antagonistic response to medium (i.e., green light) versus long (i.e., red light) wavelength stimulation resulting in receptive field color opponency. Parvo neurons often respond tonically and faithfully reflect high spatial frequency content when tested with grating stimuli. The responses of magno neurons have been described as more transient and broadband. They lack spectral sensitivity but exhibit greater sensitivity to low contrast and high temporal frequency stimulation. By comparison, the response properties of konio neurons seem more broadly distributed, with a subset responding preferentially

to the presence of short-wavelength (i.e., blue light) stimuli (Hendry and Reid 2000). This heterogeneity of konio neuron responses may in part reflect their diverse input from several types of retinal ganglion cells as well as the fact that this subgroup of neurons also receives input from the superior colliculus.

Cortical Influences on LGN

About 80% of LGN inputs arise from primary visual cortex (V1) (see Schiller et al. 1990; Sherman and Guillery 2009). This number appears surprising given the close correspondence between LGN activity and retinal stimulation. Closer examination reveals that cortical projections terminate more distally on LGN neurons and may therefore only modulate (i.e., slightly increase or decrease firing rates), rather than drive (i.e., elicit) LGN responses. For example, excitatory input from cortex can shift neuronal responses from tonic to bursting activity. At the origin of this modulatory influence are groups of neurons in layer 6 of V1 that provide stream-specific feedback to the LGN. However, other cortical visual areas also provide sparse feedback to LGN. While there is no direct evidence that cortical feedback is causing cognitive modulation of LGN neuronal activity, modulation of LGN activity has been demonstrated for top-down spatial attention (reviewed in Saalmann and Kastner 2009), possibly resulting in improved efficiency for relaying signals from LGN to cortex.

Conclusion

LGN activity tends to closely reflect its retinal input, more or less faithfully relaying visual information from eye to cortex. It thus remains

somewhat enigmatic why retinal information passes through this nucleus instead of projecting to cortex directly. One feature of the LGN is that the vast majority of its inputs are provided by cortex and other parts of the thalamus and the brain stem. These inputs selectively modulate the two eyes' outputs as they are represented in the three LGN subsystems before they reach cortex. This activity undermines the idea of the LGN as a simple relay between the eye and cortex. Indeed, significant alteration of LGN responses occurs during varying states of sleep and wakefulness, for example, and it is well established that the LGN can act as a state-dependent control that blocks, passes, or amplifies sensory information depending on the wakefulness of the individual. LGN activity has also been shown to modulate with eye movements even in the dark. Moreover, cognitive modulation of LGN activity has been shown to amplify visual signals. The convergence of several retinal ganglion cells onto single LGN neurons as well as the presence of inhibitory neurons within the LGN further suggests additional integration taking place among LGN neurons.

Definition

When individuals become passive about a situation that could be detrimental to their well-being following a previous exposure to a similar unavoidable event. Such a sense of helplessness is believed to have been adaptive in many circumstances over the course of evolutionary history but is likely to be regarded as much more problematic in the modern world due to the evolutionarily novel existence of numerous potential avenues of recourse that were conceivably unavailable in general during the prehistoric era.

Introduction

Learned helplessness was originally conceptualized as a phenomenon to describe why canines would appear to be more apathetic about evading noxious circumstances subsequent to previous experiences with comparable conditions that were unavoidable (Overmier and Seligman 1967; Seligman and Maier 1967). The seminal studies on this topic have proffered that canines, which have encountered unavoidable threats (e.g., electric jolts) in a previous experimental phase and were much more likely to defer or to refrain from eluding such stimuli in an ensuing phase (where they were avoidable) as compared to their counterparts that were not exposed to such unavoidable stressors at the outset, were actually demonstrating learned helplessness (Overmier and Seligman 1967; Seligman and Maier 1967). Subsequent to these, such a phenomenon was likewise identified in humans (e.g., Hiroto and Seligman 1975; Thornton and Jacobs 1971), and was consequently modified to account for individual differences in how one would ascribe the source of his/her sense of powerlessness (Abramson et al. 1978).

In addition, Seligman (1974) has also put forth a prominent formulation of depression which was founded on the notion of learned helplessness, while other researchers have similarly utilized such an explanatory framework to describe various other phenomena that ranged from the seemingly puzzling occurrence of certain individuals electing to remain in abusive

relationships (Walker 1977), to apathetic dysfunctional conduct in the workplace (Martinko and Gardner 1982). To these ends, a wealth of empirical research over the last few decades has since largely corroborated the existence of learned helplessness (e.g., Alloy et al. 1984; Cemalcilar et al. 2003), although apathetic responses towards threatening stimuli that have occurred over an extended period of time are now understood to be instinctual and what might instead be acquired through training is the knowledge that some of these stimuli could actually be dealt with effectively (Maier and Seligman 2016). From an evolutionary point of view, such instinctual reactions were likely adaptive at some stage in evolutionary history for them to have been widely present in the modern day.

Adaptive Functions of Helplessness

In this regard, it was contended that passive reactions in certain real-world threatening contexts could actually be beneficial for survival and subsequent reproductive success among a diverse range of living organisms in nature (Eisenstein and Carlson 1997). Indiscriminate efforts to escape a threatening situation when an immobile approach would have been more helpful could potentially make a huge difference in terms of one's survivability (Nesse 1999). Indeed, research work on a variety of animals have typically shown that passive responses in the face of a predator could significantly curtail one's risk of being preyed upon (e.g., Miyatake et al. 2004; Thompson et al. 1981). In addition, such displays of inactivity were also believed to be beneficial in riding out belligerence from more powerful conspecifics across diverse types of animals (e.g., Bilde et al. 2006; Cassill et al. 2008).

More specifically, reacting passively when encountering threats that are unavoidable was likewise conceived to be an adaptive strategy for humans (Peterson et al. 1993). Such passive responses were contended to have been advantageous in minimizing the expenditure of unnecessary physiological resources during attempts to avoid an unavoidable threat, while affording the

individual an opportunity to come through the aversive event by limiting attention to oneself (Peterson et al. 1993). Being inactive when one is being exposed to unavoidable circumstances was also believed to be helpful in promoting remedial and recuperative processes in the body that were initiated by the “ventrolateral” “periaqueductal grey (PAG) region” in the brain (Keay and Bandler 2001, p. 669), activities that could potentially be highly valuable in ensuring one’s eventual survival especially if the individual might likely sustain some forms of injury during the event.

In addition, forgoing any active attempt to evade severe psychological stressors has similarly been argued to be useful in effectively addressing a range of mental health issues (Fogle 1978). Efforts geared towards shunning away from distressing thoughts/emotions were conceived to be ineffective in addressing many different psychological issues including “stuttering, insomnia” and “sexual dysfunction” and could have the paradoxical effect of exacerbating the amount of distress associated with these maladies (Fogle 1978, p. 39). By the same token, desisting from trying to realize an unachievable outcome is an undertaking that has been shown to be linked to a lower degree of stress and a more salubrious level of physical well-being (Wrosch et al. 2007). Feeling helpless and conceding defeat when presented with a situation in which any kind of active involvement would invariably be futile in achieving one’s aims was believed to be instrumental in alleviating the cognitive/emotional discomfort in relation to recurrent unsuccessful attempts (and hence in turn improving one’s physical health) (Wrosch et al. 2007).

Taken together, maintaining/restoring to a healthier level of physical and/or psychological well-being would likely lead to an increase in one’s chances of propagating his/her genes into the future generations and thus it is logical to assume that helplessness must have evolved as an adaptive strategy for humans in certain contexts over the course of prehistory. In spite of this however, it is equally evident that responding passively to a threatening state of affairs could potentially also bring about outcomes in which the severity of resultant adverse effects might

override any functional benefit of inactivity in some other circumstances (such as when certain females opted to stay in a relationship whereby their partners have been repeatedly abusive towards them for instance) (Walker 1977). In this regard, the important question that has to be adequately addressed in order to resolve this dilemma is: why does a supposedly adaptive evolved coping mechanism (e.g., helplessness in the face of a threatening, intractable situation) seem to be so problematic at times? The answer appears to be closely related to the notion of evolutionary mismatch.

Helplessness in an Evolutionary Mismatched Environment

In virtue of evolutionary mismatch, an occurrence in which the rapidity of changes in modern environmental conditions has far exceeded the speed at which certain psychological and/or behavioral characteristics (believed to have been adaptive for much of human evolutionary history) could transform in order to adequately adjust to these recent environmental modifications, adopting a helpless coping style in the face of a threatening situation would likely be perceived as much more counterproductive in the socially advanced and technologically developed present day. Although responding helplessly to threatening stressors (especially if they are unavoidable) could potentially still engender some beneficial physical and psychological effects in an individual in the modern context, such outcomes generally pale in comparison to those that could be derived from more active means of coping because most threatening situations are now no longer generally inescapable but humans would typically still respond to them as if they are truly unavoidable as a result of evolutionary mismatch.

In other words, humans would naturally turn to evolved defensive reactions (e.g., helplessness) when confronted with threatening stressors (e.g., when one is faced with a chronic potentially dangerous situation) in general even when such coping habits might be relatively less useful in the modern world (because it takes time for humans to adapt physically and psychologically

to evolutionarily novel environmental conditions). It was believed that individuals in such predicaments could conceivably only counteract their ingrained helpless responses (e.g., by switching to a more active coping style) if they could obtain the knowledge that some of these adverse circumstances are actually likely to be avoidable at present (Maier and Seligman 2016). The possibility of helplessness being an evolutionarily mismatched coping strategy in the modern context could likely affect humans in a variety of situations.

For instance, although empirical evidence have suggested that active opposition to the perpetrator of ongoing aggression in a romantic relationship could actually bring about additional attacks on the victim in the future (arguably because the perpetrator might perceive the need to intensify the aggressive treatments in a bid to regain dominance) (Goodman et al. 2005), a passive approach is not necessarily the best course of action in the present day. Instead, other active means of coping that are increasingly provided in the modern context such as opting to reside in “a domestic violence shelter” or getting in touch with “a domestic violence victim service program” have been found to be most useful in extricating a sufferer from such a predicament (Goodkind et al. 2004, p. 528). In addition, females, for instance, were also demonstrated to be at a lower risk of being repeatedly victimized by their mistreating partners if they have a self-reliant source of income from work or a personal place of residence (resources that are increasingly attainable for females in modern societies around the world) because these females tended to have a significantly greater amount of flexibility in order to the difficult situation (Goodman et al. 2005). However, because of evolutionary mismatch, victims might generally still attempt to deal with prolonged relationship violence by reacting helplessly, and would likely only turn to more effective evolutionarily novel coping options if they are actively provided with such information and guidance in the current context.

In a similar vein, such a process could analogously be instrumental in informing a better understanding (and in turn potentially more-

effective related interventional strategies) of depression. Widely acknowledged to be one of the most explored utilizations of learned helplessness, depression has been extensively shown to be predicted by passivity when responding to a prolonged overwhelming threat (Peterson et al. 1993; Pryce et al. 2011). While behaving helplessly by forgoing any attempt to actively address an overwhelming threat could actually be evolutionarily useful for one’s continued existence in certain situations (e.g., when evading the threat appears to be an impossible task) (Eisenstein and Carlson 1997), such potentially prehistorically useful, depressive-like symptoms were significantly more likely to presently produce more harm than benefits due to the much greater range of opportunities afforded by the modern world (Trimmer et al. 2015).

For instance, although adopting a passive approach, manifested in the form of depressive symptoms, could be beneficial for recuperative purposes when one has sustained an injury (Keay and Bandler 2001; Kim 2013), such evolved responses (which would have been particularly advantageous in the ancestral context where the availability of other effective forms of therapeutic interventions were conceivably severely limited) are generally substantially inferior to more active coping methods in the medically advanced present environment. Indeed, empirical evidence have suggested that an active approach to remedying an injury via partaking in interventions afforded by modern medicine was linked to significantly enhanced well-being among those afflicted (e.g., Gottlob et al. 1999; Levendoglu et al. 2004). Providing individuals with the knowledge that prolonged suffering following an injury may actually be avoidable (by means of active engagement in the modern-day medical treatments) could therefore likely also be useful in reducing the need for helpless responses (and hence the risk of depressive symptoms) in such a situation. Similar outcomes are also expected in relation to other depression-related events (e.g., marital discord or problems at work) whereby people might be inclined to react helplessly as an evolved coping mechanism. In fact, an evolutionary mismatch perspective

could conceivably also elucidate the evolutionarily novel challenges associated with a diverse range of situations that has been linked to learned helplessness in the modern world.

Conclusion

Reacting helplessly in the face of a prolonged threat could be adaptive in minimizing the extent of harm one might experience in such a situation. Such evolved coping tendencies are believed to have aided humans in their survival over much of prehistory especially when individuals were confronted with circumstances in which active responses might actually result in a greater threat to their well-being. However, given the potentially unprecedented amount of opportunities afforded by the modern environment with regard to dealing effectively with diverse seemingly intractable problems in an active manner (that were generally much more likely to be unavailable in the ancestral context), a passive approach might not be the most useful course of action. The process of evolutionary mismatch could shed some light on why a generally sub-optimal coping strategy (by modern standards) like learned helplessness would nonetheless be adopted in the present day and how such knowledge could inform more effective methods of dealing with prolonged threatening situations.

[Learning disorder](#)

Definition

A developmental disorder that appears during school years, although it may not be recognized until later in life. It impairs one's acquisition of new knowledge even though the individual possesses a normal intelligence quotient (IQ) (American Psychiatric Association 2016).

Introduction

There are 13 categories of learning disabilities (Learning Disabilities Association of America 2017); the diagnostic criteria of which are outlined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-V) under *Learning Disorders*. Learning disabilities affect approximately 5–15% of school children and 4% of adults. Dyslexia is considered the most common learning disability, with approximately 80% of learning disabled individuals bring afflicted with it or a similar reading disability (American Psychiatric Association 2016).

Learning disabled individuals are of normal intelligence range (with an IQ around 100), and the disability cannot be because of insufficient instruction. School environment can impact those with a learning disability, as it is typically where the disability is first noticed. There is, however, special training called *Orton-Gillingham* that educators can receive to help children and adults improve their learning skills. There are also accommodations that school children can receive to help with their studies.

Orton-Gillingham Method

Drs. Samuel Orton and Anna Gillingham, developed Orton-Gillingham for students with dyslexia. Orton-Gillingham combines multi-sensory techniques with the structure of the English language, and it is beneficial not just for dyslexic students, but all students (Institute for Multi-Sensory Education 2016). Although developed in the 1930s, the Orton-Gillingham method is still widely used today.

Orton-Gillingham instructors tailor their curriculum not just to the learning disability, but to the disorders that often accompany disabilities, such as attention deficit hyperactivity disorder (ADHD). According to the Academy of Orton-Gillingham Practitioners and Educators (2012), the instructor engages multisensory teaching to convey curriculum content in an easily digestible format for the student. The multisensory side of this could include the use of chalk, writing with fingers in sandboxes, using smart boards, along with other nontraditional modes of learning. The Orton-Gillingham method also pays attention to the student's emotions, and ensures the student is motivated and self-confident. There are 12 aspects to the Orton-Gillingham approach. Other aspects include diagnostic and prescriptive lessons, direct instruction, systematic phonics, applied linguistics, linguistic competence, a systematic and structured relationship, sequential incremental and cumulative material, continuous feedback and positive reinforcement, as well as cognitive approaches that teach the student why he or she is learning.

Neurological Aspects of Learning Disabilities

While diagnosis cannot be due to a neurological incident, such as a stroke, new evidence shows there is a neurological basis to learning disabilities. Functional Magnetic Resonance Imaging (fMRI) has uncovered differences between the brains of normal range children and the brains of learning-disabled children, specifically the corpus callosum – the bundle of nerves fibers that

connects the two hemispheres of the brain (Semrud-Clikeman 2017). The corpus callosum is moderately linked to reading ability. Specifically, better readers have larger corpus callosums (Fine et al. 2007).

Learning Disabilities in Grade School

There has been much debate on whether students with a learning disability should be included in the regular classroom. While the students with learning disability do not need the special attention that children with other types of disorders require, they do need more specialized instruction than the average student does (Ford 2013). Many positive and negative aspects to having learning disabled children in standard classrooms – known as *inclusive classrooms* – have been discussed (Ford 2013). Inclusive classrooms often occur with one general educator and one special educator, although there are multiple ways that the arrangement can take place. Ford (2013) found that full inclusion in elementary school classrooms possessed moderately positive results; however, inclusive classrooms at the secondary (high school) level were not as positive as their elementary counterparts. The largest weakness in both the academic and vocational classrooms within the secondary level were attributed to the educators lacking knowledge on special education laws, along with ways to support learning disabled students. Ultimately, inclusive classrooms take time to develop, and results for individual students may vary. Direct instruction in an inclusive classroom is difficult to implement, which is why withdrawal may be needed, so it is important that the educator be able to make decisions based on each student's individual needs (Ford 2013).

Learning Disability in College

Students with a learning disability are enrolling in college at the same rate as their peers (67%) but have a lower degree completion rate (41% of students with disability versus 52% of peers) (Showers and Kinsman 2017). Family

background played a significant role in college success for students with a disability but it was mediated by student attributes. Student attributes include, but are not limited to, college preparation, degree expectation, and time of enrollment (i.e., whether or not there was a gap year taken prior to attending college).

Fullarton and Duquette (2016) conducted a case study on four college students with learning disabilities in Ontario, Canada. Although the four patients possessed a range of different learning disabilities, the researchers ultimately found that parental support and university accommodations are essential for the academic success of learning disabled students. One patient, Lauren, stated her gratitude for the support of her parents and the university she attended. It was also found that having accommodations helped her grade point average increase, and thus made her feel less “stupid”. A second patient, Ashley, was permitted to take exams in her school’s resource center, and received individual assistance with reading and math. To prepare for the challenges of college, she attended a 3-week transition program offered by the special services department of her university, and registered to receive needed accommodations. Her accommodations have helped her achieve a satisfactory grade point average. These results illustrate the importance of parental and university support in learning disabled individuals’ academic success at the postsecondary level.

Conclusion

There debate regarding education of learning disabled students continues. While the effectiveness of Orton-Gillingham is generally undisputed, training educators in the method can be costly. With that being said, other methods such as inclusion classrooms are widely debated in their usefulness, as the opinions of educators and peers can have an effect on the services provided to the disabled students. Research has shown that neither educators nor students are able to accurately explain what inclusion is, nor do they seem to be sufficiently knowledgeable on the subject (Ceylan and Aral 2016). Along with this, the conclusion

was made that educators do not prefer children who require more responsibilities in inclusive practice; although educators and peers seem to be more accepting of students with mild disability or impairment. There is still much to learn about learning disabilities, only recently have medical technologies been able to show biological differences between dyslexic children and normally developing children. As this technology improves, so will knowledge on how to properly educate students with learning disabilities.

Learning Curve

Ioulia Papageorgi
University of Nicosia, Nicosia, Cyprus

Synonyms

Learning graph; Rate of learning

Definition

A graphical representation of the rate of learning (vertical y axis) in relation to number of attempts (trials) at learning (horizontal x axis).

Introduction

A learning curve shows the progression of learning over time in repeated attempts to arrive at the solution of a problem, which may be practical (e.g., open the door of a puzzle box) or mental (e.g., memorize information, find the solution to a mathematical problem, etc.) in nature. Although developed at the end of the nineteenth century, the concept still is used in contemporary research to plot performance progression and skill acquisition over time.

Development of the Concept and First Experiments

In conditioning paradigms, a learning curve is the plot of the frequency of the conditioned response

as a function of the number of reinforcements received (Gallistel et al. 2004). The first recorded use of the concept of a learning curve was by Ebbinghaus (1885), who conducted research requiring participants to memorize a series of nonsense syllables and recorded the success over a number of trials.

Thorndike a few years later introduced his theory of learning, termed as Law of Effect (Thorndike 1898). Using puzzle boxes, he observed an animal's efforts to escape the puzzle box in order to reach food placed outside and recorded how long it took for each successful escape. He plotted the escape times in a graph that he called learning curve. Initially, learning was slow as it took each animal some time to find how to escape the puzzle box but accelerated in successive repetitions of the experiment until the escape time stabilized, resulting in an S-shaped learning curve. The S-shaped (sigmoid) learning curve appears to apply in complex learning; for example, it has recently been documented in foreign language acquisition, in the context of learning foreign words (Murre 2014).

Reflections from Contemporary Uses in Research

Whereas the first uses of the learning curve by Ebbinghaus and Thorndike reported the rate of learning at an individual level, in contemporary research learning curves are reported for groups of individuals. According to Gallistel et al. (2004), there have only been few attempts to specify quantitative properties of the learning curve in individuals, as usually what is presented are group learning curves. However, when the group-average score or performance time is plotted on a learning curve, the information is not representative of individual performance. Using a group-average learning curve confounds important independent parameters of individual learning curves such as onset latency, dynamic interval, and asymptote (Gallistel et al. 2004). Murre (2014) also challenged this practice and argued that taking the average of several learning curves

of individuals may give rise to a power function for a group's performance, even if the individual learning curves are all exponential. He focusing on limited domains of application with more explicit assumptions about the processes involved, as opposed to attempting to generate globally applicable learning functions in order to be able to generate more insightful analyses and more powerful results.

The challenges arising from reporting group learning curves are quite evident if we consider the individual differences approach in psychological research. Plotting average scores can conceal important information; any individual departures from the average are designated as "error" in mathematical models and are discarded. Glautier (2013) reported that from the perspective of an individual differences approach, the error is the data of interest. He proposed a novel associative approach to the analysis of individual learning curves to achieve a more accurate modeling of individual curves, which uses a more detailed representation of the stimuli provided by the learning environment and was able to produce better approximations to individual learning curves compared to other models.

Use of the Term in Colloquial Language: The "Steep Learning Curve"

In colloquial language, a difficult and complex procedure is often described as having a steep learning curve. Whereas in literal terms steepness in climbing a hill equates increasing difficulty, this is not the case in graphs representing learning curves. In fact, quite the opposite applies. A learning curve with a steep start represents rapid progress at the initial stages. Highly complex procedures such as surgical practice are more likely to have more gradual learning curves, with top performance level achieved only after large experience or not at all (Hopper et al. 2007).

Conclusion

The graphical representation of the rate of learning in relation to number of attempts over time is

an illustration of a learning curve. Learning curves can be plotted individually or averaged across a group. Plotting group-average plots can pose a challenge in learning and individual differences research, as important information of interest (i.e., the individual deviation from the average) is concealed. Recent literature has proposed solutions to overcome this challenge.

Definition

The acquisition of new skills or behaviors through individual effort or by replicating the actions of others.

Introduction

Imagine you have accidentally stumbled across Marty McFly's DeLorean (for the uninitiated, this is in reference to the film *Back to the Future*), and not knowing how to operate it properly, find yourself transported back over a million years to the African savannah. There you encounter a group of *Homo erectus* who are strangely unperturbed by your presence (and, more strangely, unperturbed by the presence of the DeLorean). You eventually notice that most

members of the group are able to manufacture stone hand axes and, being ignorant of how to get the DeLorean to return you to the present, quickly realize that to survive you must learn how to build your own stone tools. The key question is how do you begin doing so? Perhaps you would start by bashing two rocks together. You would quickly discover that approach won't work. What next? Perhaps you would observe someone else making a hand axe and then attempt to copy what they did. But would you copy every step in the observed sequence or would you pick and choose the components that seem to be most relevant? If you are like young children and speculatively like our *Homo erectus* cousins (Shipton and Nielsen 2015), you will precisely and deliberately copy everything you saw being done. Moreover, especially if you are like young children, you are unlikely to engage in much individual learning.

Innovation in Young Children

Building on studies undertaken with nonhuman animals, Beck and colleagues (Beck et al. 2011) investigated human children's emerging tool innovation capacities by presenting them with a narrow vertical tube containing a bucket with a hooped handle. The challenge was to get the bucket out of the tube in order to retrieve a sticker. When given a straight and hooked pipe cleaner, 4-year-olds, but not 3-year-olds, chose the hooked one above chance. Yet when given a straight pipe cleaner, a long piece of string, or some small matchsticks, 3–5-year-olds rarely took the pipe cleaner and bent it into a hook or made any other functional tool. It wasn't until children were 9 or 10 years that high levels of success were achieved. In an analogous study, 4-year-old children needed to pour water into a tube so as to float a toy to the top for it to be retrieved (Nielsen 2013). These children similarly failed to recognize the solution on their own. Testing in remote regions of South Africa suggests this inability to quickly devise solutions to novel problems is not specific to children from Western populations (Nielsen et al. 2014b).

Incongruent with the afore-reported findings, there are multiple reasons why children should engage in individual learning and innovate tools well before their primary school years. From their second year in life, children show an increasing capacity for manipulating and successfully using a variety of tools and for inferring their intended use, design, and means of categorization; and they have an emerging ability for taking what is known and extending it to novel situations, the kind of inductive reasoning necessary for tool innovation. Moreover, from 6 months of age, infants show an ability for acquiring the skills needed to use novel objects by copying others (Barr et al. 1996). It is perhaps in the latter that there lie clues as to the lack of trial-and-error-driven innovation in young children.

Imitation and Overimitation

In a landmark study, Horner and Whiten (2005) had an adult demonstrate to 3- to 4-year-old human children and wild-born chimpanzees how to extract a reward from a novel box. A bolt on the top of the box was first removed, revealing a hole into which a stick tool was repeatedly jabbed. A door located on the front of the box was then opened and the stick was used to extract the reward. Because the box was opaque, the participants could not see how what occurred inside the box was causally related to the outcome. When given their own turn with the box, both chimpanzees and children copied the model's actions, including jabbing the stick tool in the top. However, when the opaque box was substituted for a transparent box (and hence the effect of the internal actions could be identified, making it obvious that when the stick was jabbed into the top hole, it struck a barrier and made no contact with that part of the apparatus from which the reward could be retrieved), the chimpanzees now ignored the jabbing in the top hole and instead copied only the model's insertion of the tool into the front hole. They ignored the initial action which was now visibly, causally irrelevant. In contrast, the children replicated the model's entire sequence of actions, including

the visibly irrelevant insertion of the stick into the top hole.

Now known as overimitation, the tendency of young children to copy others with such high fidelity that they will incorporate visibly, causally irrelevant actions has been replicated in multiple labs and across contrasting cultural groups (Nielsen et al. 2014a; Nielsen and Tomaselli 2010). Though there is currently much research and debate in relation to the specific mechanisms and functions underlying overimitation, there is broad agreement that this phenomenon underpins children's acquisition of object-related skills that is critical in environments that feature many tools and artifacts that lack ready perceptual information about their functional significance and modes of operation. This cognitive opacity makes it challenging for novices to identify which actions or behaviors are appropriate for each artifact and which are not (Gergely and Csibra 2006). Directly and comprehensively copying others thus affords the rapid acquisition of a vast array of essential skills that have been developed and accumulated through multiple past generations.

Conclusion

When we think about the young members of our society learning it might be easy to consider them as blindly copying the acts of those around them, failing yet to have developed the cognitive resources necessary for successful individual learning. While there is an element of accuracy in this, it ignores the overwhelming value accrued to a system that can fast-track skill acquisition while avoiding the potential pitfalls of trial-and-error learning. This is not to say that young children are not capable of invention – the amazing worlds they can invent while engage in pretend play is a testament to their capacity in this regard (Pellegrini and Bjorklund 2004) – but rather highlights the strong evolutionary pressures that have come to bear on our species' peculiar learning proclivities. It is the very same ability that would enable you to make a stone hand axe at a far quicker rate than if you were to focus efforts on developing your own methods. The time saved

could then be spent trying to work out how you can get the DeLorean to take you back to the future.

Definition

Cosmides and Tooby, intellectual kindred spirits, have been leaders in both the theoretical and empirical development of modern evolutionary psychology.

Introduction

They have been leading intellectual influences in the field of evolutionary psychology for over 35 years, but it was possible that John Tooby and Leda Cosmides might have never met.

Yes, they both attended Harvard University, but Tooby's undergraduate degree in psychology (1975) was before Cosmides' graduate work in psychology during the early 1980s. Similarly, Cosmides' undergraduate degree in biology (1979) only briefly intersected with Tooby's work in behavioral biology before he moved on to biological anthropology. But then Irv DeVore got involved.

Meet Cute

Starting in 1971 and running for several decades, Irv DeVore (John Tooby's advisor) held a "Simian Seminar" in the living room of his home. These seminars were incredibly influential due to both the content and the quality of the conversations. It was informal, open to scientists at all levels (and genders), and egalitarian. "At the Simian Seminars, almost no idea or topic was too sensitive, too politically incorrect or too bawdy to be off limits. This openness was made possible by an atmosphere of mutual trust, respect, and affection, which was very deliberately cultivated by the DeVores" (Hrdy 2005, p. 90–91).

John Tooby was already DeVore's graduate student and part of this milieu when Leda Cosmides was invited to attend the Simian Seminars. She was working in both the biology and psychology departments, and the Simian Seminar was one of the few places where these two fields actually integrated well with each other. But the initial experience that Cosmides had at the Simian Seminars was one of intense frustration. She would have questions or comments about the topic being discussed, and she would try to raise her points, but another attendee – John Tooby – would chronically "steal" her thoughts before she had an opportunity to raise them.

This situation eventually led to Leda Cosmides confronting John Tooby about their like minds. Their interchanges of ideas led to collaboration, which also led to marriage. From their first joint publication in 1981 (on intragenomic conflict due to cytoplasmic DNA inheritance), only a handful of publications and presentations by one has not included the other as an author. To this day,

although their graduate students are officially in either the field of psychology or the field of anthropology, most of them consider their advisor to be a single Cosmides/Tooby unit. Together, they have advised over 25 graduate students and postdoctoral researchers.

The Ontogeny of Evolutionary Psychology

Cosmides received her PhD in Psychology in 1985, and Tooby received his PhD in Biological Anthropology in 1989. They then were both postdoctoral scholars at Stanford University with Roger Shepard and Fellows at the Center for Advanced Study in the Behavioral Sciences (1989–1990). Tooby and Cosmides then joined the faculty at the University of California, Santa Barbara, where they continue to run the Center for Evolutionary Psychology. Among the recognitions for their work, Tooby won a Presidential Young Investigator Award from the National Science Foundation (1991), and Cosmides won the American Association for the Advancement of Science Prize for Behavioral Science Research (1988) and the American Psychological Association Distinguished Scientific Award for an Early Career Contribution to Psychology (1993). They have also received an NIH Director's Pioneer Award (2005) and J. S. Guggenheim Fellowships.

Although a number of people were already conducting evolutionary research on human behavior by the 1980s, Leda Cosmides and John Tooby solidified and crystalized this approach by explicitly drawing out the reciprocal relationships between evolutionary biology, cognitive science, human evolution, anthropology, psychology, and neuroscience. According to this *integrated causal* view, researchers can develop meaningful hypotheses about specific functional designs of the human mind by considering the adaptive problems our hunter-gatherer ancestors faced over evolutionary history. In 1992, Cosmides and Tooby along with Jerry Barkow published *The Adapted Mind: Evolutionary psychology and the generation of culture*, an edited volume designed to be a state-of-the-art survey of the new field.

Several seminal chapters were included in *The Adapted Mind*, including those by Donald Symons, David Buss, Bruce Ellis, Margo Wilson and Martin Daly, Steven Pinker and Paul Bloom, Roger Shepard, and Randy Nesse and Alan Lloyd. The opening chapter by Cosmides and Tooby, however (“The Psychological Foundations of Culture”), described this sweeping view of what evolutionary psychology was and how it was done. (More recent treatments can be found in Tooby and Cosmides (2005, 2015).)

The “Psychological Foundations of Culture” chapter runs 118 pages, but a very simplified summary of the key positions includes the following:

- (a) The mind is an information processing system with a multimodular (or massively modular) structure. Specifically, the evolved architecture of the human mind includes a large number of complex, content-dependent computational mechanisms that are specialized for solving adaptive problems. Because good solutions to specific problems are tailored to the structure of those problems, there should be a large number of domain-specific cognitive mechanisms.
- (b) The relevant adaptive problems are defined by, and were shaped by, the ancestral environment of our ancestors, across the Environment of Evolutionary Adaptedness (the statistical composite of environments in which the adaptive problem existed).
- (c) Because sexual reproduction chronically recombines the genetic basis of these complex computational mechanisms in the human mind, these mechanisms must be universal and species-typical in order to be maintained.
- (d) These universal evolved mechanisms generate cross-culturally recurrent concepts and motivations (“they make certain ideas, feelings, and reactions seem reasonable, interesting, and memorable”; Tooby and Cosmides 2005), that is often referred to as “human nature.” Cultural differences arise from the input of “particular ecological, economic, demographic, and intergroup social contexts or environments” (Tooby and Cosmides

1992, p. 24) into these universal evolved mechanisms, yielding different outputs.

The chapter also contrasts these positions with those typical of the “Standard Social Science Model,” or SSSM, and explains why these SSSM positions have major problems. SSSM positions include assumptions of relatively domain-general, content-independent, and equipotential computational mechanisms in the mind, which are not necessarily tied to any evolutionary adaptive problems, and the belief that culture is an irreducible explanation (“*omnis cultura ex cultura*”).

Research Activities, Deep and Wide

Cosmides, Tooby, their graduate students, and other collaborators have published over 150 articles (<http://www.cep.ucsb.edu/publist.htm>) expanding on the theoretical foundations of evolutionary psychology and applying it across a vast range of topics.

Their most well-known application of evolutionary views to a psychological topic is the work (initially from Leda Cosmides’ dissertation; Cosmides 1985, 1989) on human reasoning about social exchanges. Like much of their research, this topic draws on insights not only from cognitive psychology (the nature of human conditional reasoning) but also from evolutionary biology (the significance of cheaters in reciprocal altruism contexts), cultural and biological anthropology (the ubiquity of this phenomena across cultures and times), and economics (the concept of gains-in-trade as a converging line of evidence). Over the years, the evolutionary theory of specialized reasoning mechanisms for social exchange (Cosmides and Tooby 1989, 1992, 2008, 2015) has been bolstered not only by additional reasoning experiments (e.g., Cosmides et al. 2010), but also by supportive findings from neuroscience (Cosmides and Tooby 2000, 2005; Stone et al. 2002), anthropology (Sugiyama et al. 2002), personality (Fiddick et al. 2016), and conceptual priming (Fiddick et al. 2017).

Additionally, research by Cosmides, Tooby, and their collaborators has dealt with a wide

range of topics across most of the major areas of psychology, consistently also drawing upon interdisciplinary insights to guide their development of theories and hypotheses. The topics addressed include: concept formation, social categorization, memory, intergroup relations, emotions, cooperation, aggression, motivations, morality, mate choice, personality, pathology, kinship, hormones, economics, political science and criminal justice, aesthetics, intelligence, and judgments under uncertainty. Throughout all these efforts, a consistent theme has been the conceptual integration of the behavioral sciences. This theme can be traced back to the opening introduction of *The Adapted Mind* (Cosmides et al. 1992), and even to Leda Cosmides' formative years in which her father was "frequently seen pounding the dinner table, insisting that interdisciplinary approaches were the future of science" (Cosmides 1994, p. 269).

Lekking

Jacob Höglund
Uppsala University, Uppsala, Sweden

Synonyms

[Arena display](#)

Definition

Aggregations of males which females visit for the purpose of mating (Höglund and Alatalo [1995](#)).

Introduction

Lekking is a collective behavior: the tendency of males to aggregate during the mating season and perform a communal display at a site restricted in space. This site is called the lek. Males often perform stereotyped displays while attending the lek, and this constitutes the lekking behavior. Females visit these aggregated male displays principally to select and mate with one or several of the males. After, mating females leave the lek and do all the parental care without male assistance. Most lekking species behave in the way just described: males aggregate and display and females select among these males. In a few role-reversed species, females display and males choose. There have been two main reasons to study leks. The first relates to the issue of the evolution of this rare mating system. What factors drive the evolution of lekking behavior? The second has to do with sexual selection. Since no male resources but gametes are transferred during mating: how come females are selective when they chose males on the leks?

Lek Evolution

Lekking is a rare mating system that has evolved independently many times during the evolution of Metazoan animals. It was first described in birds but can be found in many groups of animals including spiders, insects, fish, amphibians, reptiles, and mammals (Höglund and Alatalo [1995](#)). Many hypotheses have been put forward to explain how and why leks evolve. The most influential are (1) the hotspot hypothesis and (2) the hotshot hypothesis. The hotspot model was proposed by Jack Bradbury and coworkers (Bradbury [1981](#)) and revolves around the idea that males aggregate where the likelihood of encountering

females is maximized. Even in a uniform landscape and a hypothetical species without habitat preferences, overlapping female home ranges is enough to generate clustering behavior in males (Bradbury et al. 1989). Under certain assumptions it can be shown that males maximize female encounter rates by aggregating where female home ranges overlap the most.

The hotshot hypothesis is based on the idea that certain males (for some reason) are more attractive to females than others (Beehler and Foster 1988). In such a situation, it may benefit males to abandon solitary display and join an attractive male. If such males are not able to monopolize all females that visit them, it may pay many males to set up display adjacent to a hotshot (Höglund and Robertson 1990). These two main hypotheses for lekking are not mutually exclusive and may work in concert.

Sexual Selection and the Lek Paradox

In almost all species with lekking, it has been shown that females show strong mating preferences in favor of certain males, even if it has been surprisingly hard to pinpoint exactly which phenotypes females prefer (Seather et al. 2005). Perhaps the most common finding is that females select males successful in fighting (e.g., Alatalo et al. 1991). These consistent female mate preferences and exhaustive and costly mate sampling behavior pose an enigma to science. Given that the males do not transfer any material benefits to females, the only conceivable benefits females get from their mate choice are genetic. If so, the persistent selection imposed by females would quickly fix the male genes coding for the phenotypes females prefer, and if there is no variation among males, there is no reason for females to be selective. This is called the “lek paradox” (Borgia 1979). Numerous suggestions have been put forward to solve it including mutation-selection and mutation-drift balance, fluctuating selection in time and space, antagonistic selection between the sexes, antagonistic pleiotropic effects, and balancing selection favoring heterozygote genotypes (Radwan 2008). However, to date, empirical

studies addressing these issues remain scarce (Cornwallis and Uller 2012).

Conclusion

There are two main reasons to study lekking: (1) why do lekking evolve in some species and not in others and (2) why are females selective when the only benefit they get is genetic? These issues have puzzled evolutionary ecologists and geneticists for decades and the debate continues. A general view is that lekking tends to evolve when neither females (the limiting sex) nor resources can be defended. The issue of the lek paradox is related to the larger issue of why there is genetic variation for fitness traits that may be explained by multiple factors including those described above.

Definitions

An aggregation of sexually displaying males that females visit solely to appraise male displays and select mates. Females receive no resources from the males they mate with (only genes), and males do not provide parental care to offspring.

Introduction

Derived from the Swedish verb “leka” (“to play”), the word “lek” refers to an aggregation of sexually displaying males visited by receptive females for mate selection. Characterized by the lack of direct benefits obtained by females and the importance of male sexual displays in attaining matings, leks have become the prominent mating system to study sexual selection under natural conditions in the absence of confounding factors. As a result, few mating systems have received as much attention over the past 100 years as leks. Despite this sustained interest, there are still many questions regarding lek breeding that continue to attract researchers, including its relative rarity, the factors that determine male reproductive success and the

maintenance of genetic variation under the influence of strong directional sexual selection.

Defining Leks

Determining what does and does not constitute a lek is sometimes difficult. Classically, leks have been distinguished from other mating systems by the presence of four criteria (Bradbury 1977): (1) male display sites are aggregated within an area that is smaller than the available habitat, (2) male display sites contain no resources required by females, (3) females have the opportunity to select their mates, and (4) males do not contribute to the care of offspring. While these four criteria fit the breeding behavior of many gamebirds (for which lek breeding was originally described) almost perfectly, the discovery of many “lek like” mating systems in species whose breeding behaviors fall on a continuum of one or more of these criteria have resulted in a general relaxation of the definition of lek. For example, the second criterion – male display sites do not contain resources – is muddled on so-called “resource-based leks,” where males situate themselves near resources required by females in order to maximize female encounter rates, but do not control access to those resources. Even the definitive characteristic of a lek – aggregated males – is stretched in some species that display on “exploded leks,” where the distance between males may be so great that the aggregation may not be apparent until evaluated statistically. As such, broader definitions of leks have been proposed, such as Höglund and Alatalo’s (1995) definition that leks are an aggregation of males that females visit primarily for the purpose of fertilization. Generally, a species is considered to be lek breeding if females mate on male arenas and display some level of choice while doing so.

The Evolution of Leks

Five ecological and physiological prerequisites are thought to be required for lekking to evolve (Höglund and Alatalo 1995): (1) resources

required by females are indefensible, (2) male parental care is not required, (3) fertilization is internal, or there is no association between the chosen male and the female's oviposition site, (4) females discriminate between males, and (5) high mobility (i.e., females can accept the costs of searching out male aggregations and males can escape predators while displaying). Beyond this, the factors that lead to the adoption of lek breeding by a population appear to be varied and have received considerable attention from researchers. Why and where males aggregate are interesting questions, as each male faces potentially lower individual reproductive success while also suffering from increased fights by grouping together.

At the basic level, lek-like mating systems should evolve when males in a population cannot defend females nor the resources required by females. Furthermore, leks are likely only economical for males when females possess large home ranges and the density of females is high. In addition to these general characteristics, several hypotheses have been proposed to further explain the factors that lead to the evolution and maintenance of leks within various species (see Höglund and Alatalo 1995). Of these, four hypotheses have received considerable attention: hotshots, female preference, hotspots, and black holes. The hotshot model posits that low-quality males establish territories surrounding high-quality males in an effort to intercept females visiting those males (Beehler and Foster 1988). The female preference model suggests that females prefer to mate with clustered males, as clustering likely reduces the effort required to compare potential mates, and larger clusters may increase average male quality within the cluster (Gibson et al. 1990). The hotspot model proposes that if females possess large home ranges, leks will form in the areas of greatest home range overlap in order for males to maximize their encounter rates with females (Bradbury et al. 1986). Finally, the black hole model has been suggested for some ungulate leks (Stillman and Sutherland 1993). In this model, females in estrus are harassed by males to the point where they are driven out of the male's territory, as male harassment may lead to injury.

Females move through territories apparently at random until they eventually mate. Under these conditions, male clustering allows for higher female retention rates than solitary territories ("thus, like stars in space, females are sucked into black holes"; Höglund and Alatalo 1995, p. 170).

There is some evidence that clustering reduces predation pressure on both males and females, thus providing a selective benefit for leks over solitary displays. However, leks continue to form in captive populations under no predation pressure, and while predators may shape aspects of leks (e.g., male arrival time, lek location, they are unlikely to be the sole explanation for lek evolution.

It should be emphasized that while each of the hypotheses of lek evolution may explain the lekking behavior of some species to some degree (and are not mutually exclusive), no one theory is able to provide a single explanation for lekking; the factors that lead to lek evolution will vary based on ecological and life history characteristics on a species-to-species basis.

Taxonomic Overview

Lek breeding has been described in a wide number of taxa, both in vertebrates and invertebrates, but in a relatively low number of species (for an overview, see Höglund and Alatalo 1995). Lek breeding in invertebrates is almost wholly limited to insects (mainly Diptera), aside from fiddler crabs. Furthermore, many insects that mate in "swarms" (i.e., mass flying aggregations of insects) may reasonably be considered lek breeders despite the absence of male territories, although they are rarely referred to as such in the literature (Höglund and Alatalo 1995).

Among vertebrates, lek breeding is most commonly found in birds with 148 species confirmed to use the mating system (for a review, see Jiguet et al. 2000). In comparison, just over a dozen species of mammals have been confirmed as "true" lek breeders (i.e., meeting the four criteria of lek breeding), although more have been described with "lek like" behavior that resemble

lekking to some degree (for a review, see Toth and Parsons 2013). The mating system has also been described in some reptiles, fish, and a number of amphibians. Like swarming insects, lek breeding in amphibians may be somewhat underreported as herpetologists generally use the term “choruses” rather than “leks” when describing the aggregated male displays used by many frogs and toads.

It is possible that mobility may be a limiting factor for the evolution of leks in many taxa. For example, the relatively high numbers of lek-breeding birds may be a function of the group’s high mobility (however lek breeding may, in turn, be limited by obligate male parental care in the majority of species), and why lek breeding is generally only found in mammals that are capable of travelling large distances, such as ungulates and marine mammals (Toth and Parsons 2013). It is of interest then that only two lek-breeding species of bats have been identified to date, despite the group possessing comparable mobility to birds. However, the apparent rarity of lek breeding in bats is likely due to a general lack of knowledge of bat mating systems as a whole, and it is possible that there may be a higher proportion of lek-breeding bats than birds given that male bats – as a general rule – do not provide parental care. Further research is required.

Leks and Female Choice

Leks provide convenient systems to study sexual selection in a natural context given the apparent absence of confounding factors (i.e., the quality of males as providers and the resources they possess) on female mate choice, and male grouping allows easy assessment and comparison of male traits by females. As a result, a distinctive feature of many leks is a pronounced skew of mating success for males, with few individuals receiving the majority of matings. However, in species where males are arranged within a dominance hierarchy it is unclear if mating skews are a result of female choice or if higher-ranking males are simply able to suppress the mating opportunities of other males to a greater degree. In fact, mating skews generally become less pronounced on larger leks, which may indicate

either an inability for high-ranking males to monopolize matings from subordinates and/or more difficulty for females to assess the differences between all males effectively (Höglund and Alatalo 1995). It is also possible that intrasexual competition between females for access to desirable males may drive some females to mate with lower-quality males on larger leks and further reduce mating skew, although evidence for this is varied between species.

There are some common traits that are correlated with male reproductive success on leks across species. Behavioral traits such as display frequency (i.e., the number of displays over a given time), lek attendance (i.e., the amount of time individuals spent on the lek), and aggression frequency (i.e., the number of fights per unit time) have been found to be positively correlated with mating success, while territorial position (i.e., the distance from the geometric center of the lek) is negatively correlated with mating success across taxa (Höglund and Alatalo 1995; Fiske et al. 1998). The size of male ornaments (e.g., antlers, plumage characteristics, etc.) and male age are both positively associated with mating success (Höglund and Alatalo 1995; Fiske et al. 1998), as is body size in many species. Other predictors of male success include properties of vocal displays, which have been shown to be important in some amphibians, gamebirds, and likely bats, as well as display quality.

The Lek Paradox

Given that females choose males based on their genetic quality and that there is often high agreement among females during mate selection, genetic variation should eventually be exhausted in the population and remove the benefits of female choice. However, persistent female choice continues in lekking populations across generations. This is known as the “lek paradox” and remains one of the most puzzling aspects of lek breeding.

There are several proposed solutions to the lek paradox. Some researchers have suggested “genetic capture” as an explanation (e.g., Rowe and Houle

1996); given that the male traits under female selection are condition dependent and that male condition is in turn encoded by a suite of genes (e.g., those controlling body size, metabolism, etc.), there is likely sufficient genetic variation present in these myriad regions to resist directional female selection. Additionally, mutations and gene flow will also maintain genetic variation and oppose runaway selection by females (Rowe and Houle 1996). Another (not mutually exclusive) hypothesis posits that the effects of predators, parasitic matings, and intrasexual competition can diversify male mating success enough that low-quality males continue to exist in the population, even if there is uniform assessment of male quality by females (e.g., Hamilton et al. 2006). However, empirical tests of such hypotheses are rare and future work is required to determine which explanations represent likely resolutions to the lek paradox.

Conclusions

Leks continue to provide rich systems for the study of male courtship behavior and female selection of good genes in varied taxa. The study of lek breeding will benefit from examining lek breeding in species beyond ungulates and gamebirds, as well as experiments investigating factors that influence lek formation, female choice, and the maintenance of genetic variation in lekking populations.

Definition

Unfamiliar theories that do not fit the dominant evolutionary theories of homosexuality.

Introduction

There are a number of evolutionary hypotheses about homosexuality that do not fit either of the three main hypotheses discussed elsewhere in this encyclopedia (► [Kin Selection Hypothesis](#); ► [Sexually Antagonistic Hypothesis](#)). Many of these lesser-known hypotheses were initially introduced to explain the occurrence of homosexuality in nonhuman animal species, which may perhaps account for the fact that they tend to be less familiar to evolutionary psychologists. Some of these hypotheses cannot be made to bear on human homosexuality (e.g., *reproductive suppression hypothesis*); others *could* perhaps be made relevant to human homosexuality (e.g., *sperm competition hypothesis*); still others *have* in fact so been applied (e.g., *dominance hierarchy hypothesis*). Finally, there are evolutionary hypotheses that originated in the context of human homosexuality and that do not apply to animal homosexuality (e.g., *kin influence hypothesis*).

Many of the hypotheses discussed below have been the target of criticism from both within and without the evolutionary sciences. First of all, some of them are little more than ► [Just So Stories](#), being notoriously difficult to test, particularly in wild animal species or in human populations. According to Dawkins (1982, p. 37), the *sneaky male hypothesis* is a case in point. Secondly, explaining what some aspect of homosexuality accomplishes is often a far cry from revealing its evolutionary roots: Not all adaptive traits are adaptations. Thirdly, homosexuality can be a complex phenomenon, ranging from a variety of sexual behaviors, such as genital touching, mutual masturbation or copulation, overdesires, and preferences to lifelong orientations. Many of the hypotheses at hand fail to explain what aspects are being targeted – a shortcoming that often leads to confusion and

misunderstanding. Fourthly and finally, evolutionary scientists are often biased toward the “passive” partner in homosexual encounters in animals, while ignoring the “active” partner, i.e., the one who penetrates during a coitus, the one who initiates a series of sexual behaviors, or the one who takes the lead in a courtship session (Fausto-Sterling 2000). A similar critique could be directed against (evolutionary) biological explanations of human homosexuality.

It is important to note that many of these hypotheses are mutually compatible, as they are with nonevolutionary explanations of homosexuality, such as genetic, endocrinological, and even social constructivist explanations (Adriaens and De Block 2006). Like many other organismal traits, mounting and other homosexual behaviors may indeed serve several functions, either simultaneously or successively. The human skin, for example, protects the insides while at the same time regulating body temperature.

There are many ways to classify evolutionary hypotheses about homosexuality. This entry builds on a common tripartition in the evolutionary sciences, identifying and explaining homosexuality as an adaptation, a by-product, or a dysfunction.

Adaptationist Hypotheses

An adaptation is a functional feature of an organism – a feature that evolved through natural selection because it enabled the organism’s ancestors to produce more offspring than rival organisms lacking the same trait. On first thoughts it may seem odd to conceptualize homosexuality as an evolutionary adaptation, given that it is often said to be associated with decreased reproductive success. Now this association may perhaps be true for some aspects of homosexuality, such as homosexual preferences, but it certainly need not be true for other aspects, such as homosexual behaviors and desires. Adaptationist hypotheses about homosexuality can be classified according to whom actually benefits from being involved in a homosexual encounter: the active partner, the passive partner, or both. For each of these options, a number of exemplary hypotheses will be discussed.

In the past half a century, evolutionary scientists have suggested numerous adaptive functions for the active partner's homosexual behaviors and desires. A first hypothesis, the **reproductive suppression hypothesis**, is based on the observation that, in a number of nonhuman animal species, homosexual mounting serves the mounting partner's attempts to reduce the mountee's reproductive success. Mounting may achieve this goal in various ways. In the most straightforward scenario such behavior is part of a harassment strategy aimed at disrupting the mountee's heterosexual reproductive activities. Some evidence shows, for example, that female American bison mount each other to disturb the bull's courtship attempts. In some primate species, such as langur monkeys, estrous females are disproportionately more often mounted by other females (Sommer et al. 2006).

One of the main problems with the **reproductive suppression hypothesis** is that some of its supportive evidence can also be explained by means of other evolutionary hypotheses, such as the **signal mounting hypothesis**. Secondly, it isn't clear why natural selection would favor homosexual mounting as an intrasexual competition tactic if there are obvious and more efficient options available, such as chasing or biting. The latter objection can be met, however, by referring to evidence documenting long-term negative effects (of being mounted) on a mountee's reproductive success. In gray wolves and European rabbits, for example, female-female mounting with pelvic thrusting often causes a kind of pseudopregnancy, i.e., an extension of the mountee's diestrous phase, which suppresses a number of subsequent cycles (Asa and Valdespino 1998). It is doubtful, however, whether the **reproductive suppression hypothesis** would enable one to understand any aspect of human homosexuality (but see MacIntyre and Estep (1993), who argue that homosexual behavior of heterosexuals carrying "a gay gene" could be seen as a reproductive suppression strategy).

A closely related hypothesis, the **dominance hierarchy hypothesis**, fits homosexuality in with findings on dominance behavior in social species. It holds that homosexual contacts are ritualized

behaviors that mirror, establish, or confirm an individual's social position. Penetrating, for example, is an expression of dominance and being penetrated an expression of submission. While this seems to be true for some animal species, such as female stump-tail macaques (Vasey and Sommer 2006), it does not work for others, such as deer, in which dominant individuals are more frequently mounted by lower-ranking rivals than vice versa (Bartoš and Holečková 2006). To complicate matters, it appears that, in some species, high-ranking males take on a dominant position in some homosexual activities and a subordinate position in other such activities. Moreover, the dominance hypothesis only applies to aspects of homosexuality that lend themselves to being an expression of dominance or submission, such as mounting or pelvic thrusting. Such activities, however, are only a limited subset of the total homosexual behavioral repertoire, both in humans and in other animals. What about kissing, masturbation, or courtship behaviors?

In human populations, especially in times past and in non-Western settings, evidence seems to confirm some of the central tenets of the **dominance hierarchy hypothesis**. One of these tenets is that sexual roles are differentiated according to social rank. Historical research reveals indeed that socially asymmetrical relationships between adult and adolescent males always involved a clear-cut sexual division of labor. In classical antiquity, in the Samurai culture in medieval and early modern Japan, in the Islamic world, and in Renaissance Florence, to name just a few, male homosexuality was so common as to be universal. But it was always structured by age, meaning the adult male was expected to consistently fulfill the "active" role in sexual activities. Until well into the twentieth century, a similar sexual tradition could be found among black South African migrant diamond miners. Adult males, some of whom were married back home, took on a so-called boy-wife for both domestic and sexual purposes. Such relationships were governed by a distinct set of rules, including the tenet that "proper wifely behavior did not include ejaculation by the youth, or any kind of sexual reciprocity" (Murray 2000, p. 166).

Contemporary human homosexual relationships, especially in the West, are much more socially egalitarian, so the **dominance hierarchy hypothesis** does not promise well in this context. There is some evidence, however, that homosexual activities in sexually segregated human populations may be reminiscent of dominance behavior. Anecdotal evidence shows, for example, that some male prison inmates in Britain and America, regardless of their sexual orientation before they were incarcerated, are being held as “wife” by their “husband.” A “wife” is expected to fulfill much the same submissive role as the South African boy-wives mentioned earlier, including cooking, washing, and having sex with their “husband.” Some of these men are even forced to take on a female name and identity (Walshe 2012). Criminologists consider prison rape to be an act of violence and power (O'Donnell 2004) – a view that dovetails with the **dominance hierarchy hypothesis**. It is important to note, however, that it is unclear what role the current adaptive value of some aspects of homosexuality has had in driving the evolution of homosexuality as such.

These two adaptationist hypotheses focus exclusively on the adaptive value of the active partner's behavior, which usually consists of penetrating or mounting. Yet sometimes such behavior serves the reproductive success of the *passive* partner, who then acts as (active) instigator in the encounter.

A first hypothesis that fits this description is the **sneaky male hypothesis**. It holds that, in some animal species, some subordinate males mimic salient parts of the female phenotype, in order to appease the dominant male's aggression and to invite mounting or penetrating on his behalf. Thus they, i.e., subordinate males, are able to get full access to the dominant male's territory with all its associated advantages, including protection, food, and access to the latter's females. In bluegill sunfish, for example, males come in three morphological categories – a classification based on two phenotypical characteristics: body size (small, medium, or large) and coloration (light, dark with vertical bars, light with yellow-orange breast) (Roughgarden 2009). Medium males

closely resemble young females, both in size and coloration. During spawning, some large males allow medium males to enter their territory. Both males extensively engage in courtship activities, first with each other and then with a female. As the female releases her eggs, both males fertilize them.

The medium male's reproductive strategy has often been seen as a form of deceit, made possible by the large male's inability to distinguish between females and medium males. Critics have questioned this inability, observing that sunfish have great eyesight. Moreover, even if large males would initially be deceived by the size and coloration of medium males, it is unlikely that the deceit wouldn't come out over the course of their joint activities. According to Roughgarden (2009), both males enjoy a cooperative relationship based on same-sex sexual attraction – a supposition that fits the story of male sunfish homosexuality in with the ► **“Alliance formation theory”** discussed elsewhere in this encyclopedia.

The **sneaky male hypothesis** has also been cited as an explanation for (some kinds of) human homosexuality (Jeffery 2015). Male homosexuals, for example, are often considered “a girl's best friend,” and they are not perceived as sexual competitors by their heterosexual congeners. The main problem with this hypothesis is that it is at least unclear whether, historically, male homosexuals have always had easy access to women, and whether heterosexual men have always been as tolerant to them as they are today, at least in Western countries. Another issue is why being homosexual would be the best way to obtain sneak copulations. If anything, it seems to decrease the possibility of heterosexual intercourse.

The **sperm competition hypothesis** is another adaptationist hypothesis that conceptualizes (male) homosexuality as a trait that benefits the passive partner's reproductive success. In a heterosexual context, sperm competition occurs whenever the sperm cells of two or more males compete to fertilize an ovum, which happens to be the case when a female mates with multiple males over a brief period of time. In some bird species, homosexual behavior has been shown to affect

this competition. Mountees solicit rival males to mount them because allowing themselves to be mounted and penetrated makes the mounters waste their sperm (Birkhead and Møller 1992). In some species mountees proceed by mimicking typically female traits, in which case the *sperm competition hypothesis* can be classified as part of the *sneaky male hypothesis*. Evolutionary psychologists have also invoked sperm competition to explain a number of *human* characteristics, including male homosexuality (Pound et al. 2006). However, the resulting variant of the *sperm competition hypothesis* conceptualizes homosexuality as a by-product, rather than an adaptation, and so it will be discussed in the next section.

Many of the hypotheses, discussed so far, are based on the assumption that homosexuality has adaptive value only for one of the two partners involved. While this may indeed be the case for some instances of homosexuality, many homosexual activities seem to be enjoyed by both partners, and there may be reasons to assume that they do so because these activities are of benefit to both. Regarding the dominance hierarchy hypothesis, for example, Vasey and Sommer (2006, p. 22) note that “mounts by dominant individuals are sometimes associated with affiliative behavior and solicitations by the mountee (...) which, in a heterosexual context, would be taken as a sign that indicates sexual interest.” Given that homosexual encounters are often part of a joint venture, it seems rather naive to consistently distinguish between “active” and “passive” partners. A third and final category of adaptationist hypotheses meets exactly these objections.

A representative example of this third category is the *sexual practice hypothesis*. This hypothesis holds that homosexual behavior among juveniles helps them to practice sexual skills, such as motor and social skills, that may prove helpful in heterosexual contacts throughout adult life. This hypothesis has received support in many mammal species, ranging from rodents over ungulates to dolphins and primates (for an overview, see Poiani 2010). Homosexual play-mounting is an excellent example of the claim that one and the same behavior can fulfill a number of functions, either

simultaneously or successively, in that play-mounting among male juveniles also seems to help in establishing or reinforcing dominance relationships and alliances.

In humans, juvenile sex play, both among siblings and nonsiblings, has been observed to occur in populations as diverse as Trobriand Islanders and North-American undergraduates (quoted in Poiani 2010), even though there seems to be some cross-cultural variation as to its prevalence. Greenwald and Leitenberg (1989) reported that, at least for American boys, homosexual play behavior was more common than heterosexual play behavior. Much like in other animal species, however, juvenile homosexual play does not seem to be a precursor to the development of homosexuality in later life (Poiani 2010). Finkelhor (1980) explains these findings by means of both the *sexual practice hypothesis* and the *dominance hierarchy hypothesis*.

By-Product Hypotheses

Stephen J. Gould and Richard Lewontin (1979) famously argued that many of an organism's features are not adaptations. In their view, some evolutionary theorists tend to underestimate the many constraints imposed on the powers of natural selection, thus limiting the amount of adaptive design in nature. Some adaptations, for example, inevitably come with one or more by-products that are at least initially nonadaptive.

What could it mean to say that some aspects of homosexuality are to be considered as by-products of an evolutionary adaptation? A first hypothesis that fits this description is the *hypersexuality hypothesis*, which holds that some homosexual behaviors (and perhaps some other aspects of homosexuality, such as desires) are by-products of an individual's above-average level of sexual activity and interest (Poiani 2010). Given that hypersexuality is by definition a relative concept, determining whether it is indeed an evolutionary adaptation, as the *hypersexuality hypothesis* assumes, will require a thorough knowledge of breeding patterns and various ecological parameters of the species involved.

In many animal species, hypersexuality is a temporary trait that covaries with the breeding

season(s). During this time, sexual activities are much more abundant than during the nonbreeding season, and they often include homosexual behaviors (Bagemihl 1999). Sometimes these behaviors are facilitated by specific circumstances, such as a species' inability to detect sex differences. Frogs provide a good example. In the breeding season, males will mate with anything that roughly resembles a female, sometimes contenting themselves with females of other species, with males of their own species, or parts of the human observer's body or equipment. Hypersexuality can also lead to homosexuality in the absence of available and suitable partners of the opposite sex. Historically, many instances of animal homosexuality have been explained as the outcome of a Hobson's choice, i.e., a free choice in which only one option is offered. The popularity of this explanation dates back to classical antiquity, where various authors reported instances of homosexual behavior in sex-segregated populations of domesticated and captive animals (Bagemihl 1999).

Hypersexuality can also be considered as a permanent trait, in which case the intensity of an individual's sexual activity and interest is above average on the level of the population *across the individual's mature lifespan*. Levels of sexual activity and interest are known to vary considerably across individuals, particularly in humans. If the **hypersexuality hypothesis** is to account for (some instances of) human homosexuality, then one should expect at least some homosexuals to be hypersexual, which may indeed be the case (Bell and Weinberg 1978). Much like in non-human animal species, the connection between hypersexuality and human homosexuality may be facilitated by certain circumstances, including a biased sex ratio (Poiani 2010).

Another by-product hypothesis about the evolution of homosexuality is the **hypervariability hypothesis**. Hamer and Copeland (1994) have suggested that homosexuality has not been weeded out of the gene pool because it is linked to hypervariable DNA sequences, i.e., sequences in which spontaneous mutations are conspicuously more common than elsewhere in our DNA. There are at least three problems with this hypothesis. First of all, there is little or no research

on the nature of the advantage related to having a flexible genome. For the **hypervariability hypothesis** to be an exemplification of a by-product hypothesis, the trait with which homosexuality is connected needs to be an adaptation. But it remains unclear what the adaptive value of hypervariability would be. Secondly, decades of intensive genetic research have produced very little tangible suggestions as to which DNA regions are involved in the development of homosexuality. Thirdly and most importantly, there is currently no evidence that any of the parts of our DNA that have in the past been associated with homosexuality is in fact a hypervariable DNA sequence.

A third by-product hypothesis about the evolution of homosexuality is a variant of the **sperm competition hypothesis** discussed above. Pound et al. (2006) speculate, for example, that homosexual arousal in men may be caused by (their attentiveness for) cues related to increased sperm competition risk. Pound's earlier evidence (quoted in Pound et al. 2006) indicates that men prefer polyandrous pornography, in which a woman has sex with multiple men at the same time, over harem pornography, in which a man has sex with multiple women at the same time. This preference doesn't seem consistent with the cold reality of paternity uncertainty, unless one invokes a central tenet of the sperm competition hypothesis, i.e., that the presence of rival males stimulates sexual arousal because it increases a given man's number of sperm delivered when copulation ensues, and thus his chances of conception.

Pound's **sperm competition hypothesis** of human male homosexuality leaves many questions unanswered. It is unclear, for example, exactly how homosexuality is to be coordinated with the arousal produced by the presence of rival males. Pound et al. (2006, p. 14) write that the arousal occurs "in response to other men," which obviously differs from saying that it is *oriented towards* them. It seems that their argument is lacking a crucial step, which could consist, for example, in claiming that human male homosexuality is due to a dysfunction in the mechanism regulating sexual arousal in the context of sperm

competition. If that is the case, however, their **sperm competition hypothesis** would be a dysfunction hypothesis, rather than a by-product hypothesis, as the authors themselves would have it. They also mention another hypothesis based on sperm competition (MacIntyre and Estep 1993), which conceptualizes male homosexuality as a (specific kind of) by-product of sperm superiority in heterosexual men carrying gay genes. As such, the sperm competition hypothesis would be a variant of a class of hypotheses discussed elsewhere in this encyclopedia. A general objection to both of these sperm competition hypotheses is that there is considerable debate about the general importance of sperm competition as a selective force in human evolution (Buller 2005).

A fourth and final by-product hypothesis is based on the fraternal birth order (FBO) effect and might therefore be dubbed the **birth order hypothesis**. One of the few reliable epidemiological findings in research on homosexuality, the FBO effect implies a positive correlation between male homosexuality and number of (biological) older brothers. The effect does not hold for the relationship between male homosexuality and number of older *sisters* nor between *female* homosexuality and number of any type of sibling. With further evidence suggesting that the FBO effect is initiated during fetal development, Blanchard and Bogaert (1996) came up with the maternal immune hypothesis to explain the underlying mechanism. Their hypothesis holds that a succession of male fetuses increasingly confronts the mother with specific male antigens, thus triggering an immune response on her part. This response, in its turn, affects the sexual differentiation of her later born son's brain in such a way as to make it more likely for him to develop a homosexual orientation.

Even in a recent review, Bogaert and Skorska (2011) do not examine the question whether the mother's immune response is to be considered as an adaptation. If it is, however, then the FBO effect could be seen as part of an evolutionary hypothesis, explaining male homosexuality in humans as an evolutionary by-product of an adaptation, i.e., a mother's immune reaction during pregnancy. The main problem of the **birth order**

hypothesis concerns exactly this reliance on the maternal immune hypothesis. First of all, even though the latter is certainly testable, it has not, to date, been tested yet. Secondly and more importantly, the maternal immune hypothesis relies on research about structural differences in the brains of heterosexuals and homosexuals, which has aroused fierce criticism in the past quarter century (Stein 1999).

Dysfunction Hypotheses

A third and final category of evolutionary hypotheses considers homosexual behaviors, desires, preferences, and orientations as manifestations of a disruption, rather than a by-product, of some adaptation. Dysfunction hypotheses explain the evolutionary persistence of homosexuality as resulting from the fact that the adaptive mechanisms involved in regulating sexual behaviors and mental states are not always able to perform the function that natural selection designed them to.

Some dysfunction hypotheses are closely related to by-product hypotheses. The **hypersexuality hypothesis**, for example, considers homosexuality to be a by-product of hypersexuality, which in turn is assumed to be an adaptation. In some cases, however, hypersexuality and its connection with homosexuality are the result of a dysfunction. Experimenting with animals shows, for example, that their level of sexual activity and interest can be manipulated by inflicting damage on specific parts of their central nervous system that are assumed to be involved in regulating their sexuality (for an overview, see Poiani 2010, pp. 220–222). Here the **hypersexuality hypothesis** is to be considered as a dysfunction hypothesis.

Apart from lesions, pathogens are also important in understanding why mechanisms dysfunction. Infectious agents, such as bacteria, viruses, and parasitic worms, play at least some part in the etiology of many physical disorders and some mental disorders, such as schizophrenia and tertiary syphilis (Ledgerwood et al. 2003). Some researchers have defended the view that it would at least be worthwhile to consider the hypothesis that homosexuality would also be caused, in part, by some infectious agent (Cochran et al. 2000). This **contagion hypothesis** speculates that infections could cause a dysfunction in any of the

mechanisms involved in the development of brain structures that regulate sexual behavior and desire. To strengthen their case, adherents refer both to the shortcomings of evolutionary hypotheses about homosexuality and to a number of findings that they consider to be supportive, such as low identical twin concordance, geographical variation in incidence, and neurological differences between homosexuals and heterosexuals. One problem with the *contagion hypothesis* is that many of these “findings” are at least controversial (see above). Another problem is that no infectious agent has as yet been identified in the etiology of homosexuality.

A third and final dysfunction hypothesis, the *kin influence hypothesis* (Adriaens et al. 2012), is one of the few lesser-known evolutionary scenarios about homosexuality that do not originate in research on nonhuman animals. Indeed, this hypothesis focuses on an aspect of homosexuality that is generally considered to be rather exceptional in the animal kingdom and is commonly referred to as “modern homosexuality”: long-term, exclusive, and egalitarian homosexual relationships. It is this aspect of homosexuality with which members of WEIRD societies (Henrich et al. 2010) are most familiar. There is considerable debate about the prevalence of such relationships in times past and in contemporary non-Western countries, but there is also a consensus that they have become much more common than ever in the past 150 years (Murray 2000).

The *kin influence hypothesis* relates this rise to the process of economic development and the ensuing disintegration of traditional family ties. Research on small-scale societies reveals that family ties come with a set of norms and beliefs about sexuality and reproduction, which conform to the prediction of Darwinian theory that members of a family-based community will tend to maximize their (inclusive) fitness. Economic development triggers the construction of new sexual norms and beliefs that increasingly diverge from that which is consistent with achieving reproductive success. One such belief is that it is prudent to limit family size – a belief that resulted in a rapid decline in the fertility of most Western populations since 1850. Concomitantly, acceptance of nonreproductive aspects of sexuality has

been on the rise, with ever more people indicating that they believe homosexuality to be justified. According to *the kin influence hypothesis*, these cultural changes have set the scene for a modern kind of homosexuality to begin to flourish. Considered here as a dysfunction hypothesis, it holds that the rise of modern homosexuality is due to a breakdown in the functioning of the mechanisms involved in adopting fitness-maximizing reproductive norms.

Of course, the kin influence hypothesis only accounts for a very specific aspect of homosexuality and that other aspects may rightly be considered as evolutionary adaptations or by-products. Indeed, one of the recurrent erroneous assumptions in evolutionary thinking about homosexuality is that modern homosexuality is somehow representative of all aspects of homosexuality at all times and in all places (Adriaens et al. 2012).

Conclusion

Clearly, there is no lack of hypotheses explaining the evolution of homosexuality, both in humans and in other animals. An optimist would probably consider this abundance as a sign of the imaginative power of evolutionary scientists; a cynic, by contrast, would probably dismiss their scenarios as mere just-so stories. As always, the truth is somewhere in the middle. Some (parts of some) hypotheses have indeed been corroborated or falsified by empirical findings. Moreover, some researchers have indicated that their hypotheses can only account for a specific aspect of homosexuality, or a specific part of the homosexual population, thus leaving the door open for the coexistence of multiple explanations. It is vital, however, that existing hypotheses continue to be tested rigorously against the norms of evolutionary empirical research.

Lev Vygotsky

Ekaterina Zavershneva¹ and René van der Veer²

¹Moscow State University, Moscow, Russia

²University of Leiden, Leiden, The Netherlands

Definition

Lev Vygotsky is an author and a researcher in the area of general, developmental and educational psychology.

Introduction

Lev Semyonovich Vygotsky (real name – Lev Simkhovich Vygodskiy) was born on November 17 (6), 1896 in Orsha (now the territory of Belarus) to the family of the banker Simkha Leibovich Vygodskiy. Vygotsky spent his childhood and youth in Gomel, where he received comprehensive education, first at home, then at a private Jewish gymnasium. In 1913 Vygotsky started to study law at Moscow University; he also attended classes at the faculty of history and philology of Shanyavsky People's University, where he wrote the *Tragedy of Hamlet* as a graduate thesis. At the time he was involved in literature and theater, about which he would publish more than eighty reviews. During this period he also was in ideological opposition to Marxism and tried to realize himself in essays on Jewish national politics (Zavershneva and Van der Veer 2018).

In the revolutionary years of 1917–1918 he moved from sympathy to Judaism to accepting Marxism, while remaining faithful to the philosophy of Spinoza. Having returned to Gomel in 1917, Vygotsky became one of the central figures of Gomel cultural life and taught the humanities. Vygotsky retained his interest in art until the end of his life and devoted his dissertation *The Psychology of Art* to the problem of the scientific explanation of aesthetic reactions.

In 1923 Vygotsky went to work in the Gomel Teacher Training College, where he conducted his first psychological research. In 1924 at the invitation of Aleksandr Luria he moved to Moscow and later combined scientific and teaching activities in psychological, educational and medical institutions in Moscow, Leningrad and Kharkov. In a short time Vygotsky created a new direction in psychology, which afterwards became known as cultural-historical psychology, and founded a major scientific school (among his associates were Aleksey Leontiev, Aleksandr Luria, Daniil El'konin and others). His work influenced developmental and educational psychology, the psychology of cognitive processes, child psychology, psycholinguistics and neuropsychology. However, the intense activities had a disastrous effect on Vygotsky's health: he suffered from

tuberculosis since 1920 and died on 11 June, 1934 at the age of 37.

Vygotsky's death was followed by a long period of silence connected with an unofficial ban on his publications in the USSR, which ended with the republication of part of his writings in the 1960s and 1980s. The first biographies of the scientist were published in the 1990s (Van der Veer and Valsiner 1991; Vygodskaya and Lifanova 1996) and his ideas acquired new adherents both in Russia and elsewhere (see Cole 1996; Miller 2011; Wertsch 1985; Yasnitsky et al. 2014). Today Vygotsky counts as one of the better-known psychologists of the twentieth century (Haggblom et al. 2002).

Main Ideas and Concepts

At the beginning of his career (1924–1925) Vygotsky toyed with the concepts of reflexology and behaviorism, but the greatest influence on him was exerted by, respectively, the founder of topological psychology Kurt Lewin, the psychologist Jean Piaget, and the Gestalt psychologists Kurt Koffka and Wolfgang Köhler. During the period of “instrumental psychology” (1926–1929), the concepts of sign operation and higher mental functions (HMF) were in the center of his theory (Vygotsky 1997). In the transitional period (1930–1931), and in the period of the psychology of dynamic semantic systems (1932–1934), these notions were supplemented by the concepts of word meaning, sense and semantic field and the study of verbal thinking became the main channel of Vygotsky's thought.

According to Vygotsky, mental processes should be studied in development; for this purpose he elaborated an experimental-genetic method in which mental processes are not simply observed, but also formed. Vygotsky defined his approach as “peak psychology,” focused at studying higher forms of mind, and argued that the mechanisms of human development are not genetically inherited, but introduced by culture and society. Language is the main tool of transforming natural mind into higher mind; it allows

accumulating and transmitting the experience of generations. With the help of speech and verbal thinking the individual gradually becomes an autonomous person capable of free choice.

Sign Operation

In contrast to animal mind, which is based on maturation and adaptation to the environment, human mind is also formed with the help of auxiliary cultural means (speech and writing, the number system, cultural artifacts), which are developed in communication with other people and allow to master human behavior. A system of HMF, developing in the process of anthropogenesis and ontogenesis, arises on the basis of natural functions through their mediation by psychological tools. Thus, voluntary memory in its simplest form is represented by making a knot in a handkerchief, the index gesture is the simplest means for regulating attention, and throwing dice is a prototype of volitional action. Primitive forms of sign operation are based on external material means (a knot, the index finger, a die), however, the mature mind is characterized by the use of internal means of regulation.

The Sociogenetic Law

During ontogenesis the child acquires social forms of behavior and begins to apply them to himself. For example, when he learns to speak, his speech activity is aimed at communicating with other people and is mostly external. Only at a certain stage of development the child uses speech to communicate with himself: first externally, talking aloud, and then internally – as a means of reflection. This process, called interiorisation, is defined as the creation of internal mental structures by “transferring inward” modes of behavior assimilated in the social situation of development.

According to Vygotsky, each HMF passes through three stages:

1. The HMF arises as an interpsychological function, distributed between people and controlled from outside with the help of external means (the adult organizes the activity of the child by pointing to objects, naming them, etc.);

2. The HMF becomes an extrapsychological function: the child controls himself with external means (speaking aloud, counting on his fingers, etc.);
3. Finally, the HMF turns into an intrapsychological function: the external means become internal (inner speech, mental calculations, etc.).

HMF do not work in isolation, they are connected in an integral system. In the process of ontogenesis, the primary, innate connections between functions are destroyed and new, artificial connections are created. They then form a system that can be deliberately changed and in which one function dominates and guides the others. Mature mind is characterized by the presence of flexible and differentiated psychological systems that can be adapted to specific tasks.

The Zone of Proximal Development (ZPD)

The notion of the ZPD appears in lectures read by Vygotsky in the early 1930s, where he argued that teaching should stimulate internal change: it should run ahead of development, rather than follow it. Taking into account the child's actual level of development, the adult must introduce cultural means and teach the child how to use them. This transfer of cultural means takes place in the ZPD, which characterizes the processes that are ripening, but have not yet fully matured. In practical diagnostics, the ZPD is defined as the difference between the level of the child's independent problem solving and his level of problem solving in collaboration with an adult.

Ontogenesis of Verbal Thinking

According to Vygotsky, thinking and speech have different genetic roots, and the relationship between them is variable in phylo-, onto- and functional genesis. In animals, intellect and speech develop independently of each other, but in the process of anthropogenesis these functions merge into the single whole of verbal thinking, which is no longer a natural, but a socio-historical form of behavior.

In the early 1930s Vygotsky proceeded to study word meaning as a unit of verbal

thinking, defining meaning as the internal structure of the sign operation. With the help of the double stimulation technique (in the form of the Vygotsky–Sakharov test, also known as the Kasanin–Hanfmann test), Vygotsky showed how meaning, passing through various stages (syncretic whole, complex, and concept), gradually acquires a stable structure and becomes less dependent on situational factors. The highest form of meaning – the concept – is based on abstraction, free of concrete content, and is not tied to sensory impressions. The concepts acquired by the adult form a network; this internal plane of generalization Vygotsky called the semantic field. It serves as the basis of volitional action and connects cognitive and affective systems.

Egocentric Speech

The term “egocentric speech” for speech addressed to oneself, was proposed by Piaget, whose work served as a starting point for a series of experimental studies by Vygotsky's research group. Contrary to Piaget's assumption that egocentric speech is nothing more than an accompaniment to the child's actions, Vygotsky argued that it has a special function in mental development. In accordance with the sociogenetic law, speech arises as an interpsychological process and then goes through an extra-psychological stage, when the external means (the sounding word) serves to objectify behavior and makes it easier to manage. As the child develops, egocentric speech shifts to the subvocal plane and then, at the intrapsychological stage, becomes inner speech.

Inner Speech and Semantic Dynamics

Thought is not expressed but formed in the word, asserted Vygotsky after the linguist Aleksandr Potebnya. He compared the thought to a hovering cloud, which gushes a shower of words and motivation to the wind that puts the cloud in motion. With the help of this metaphor, Vygotsky presented verbal thinking as a complex dynamic whole, passing through several planes in its development: (1) motivation, (2) thought, (3) inner speech, and (4) vocal speech (Vygotsky 1987). Every single utterance, then, is the result of series of inner processes that defy direct observation.

Using indirect evidence, Vygotsky speculated that inner speech has a number of distinctive features: sense prevails over meaning; it is predicative (the subject is often omitted), abbreviated and idiomatic (intelligible only to the speaker), agglutinated, and detached from vocal speech. In the last years of his life, Vygotsky intended to explore the semantic dynamics of consciousness, but his plans were not realized.

Conclusion

Among the undisputable achievements of Vygotsky's approach are the elaboration of the idea of the sociocultural determination of human development, the experimental-genetic method, the introduction of a number of fundamental categories (HMF, ZPD) and principles (sign mediation, the systemic and semantic structure of consciousness). The practical importance of his approach has been shown in developmental and educational psychology and in the psychology of cognition. In other areas (motivation, emotion, volition, consciousness, and personality) the value of his ideas still needs to be explored. But it seems psychology has not yet exhausted the potential of Vygotsky's cultural-historical approach.

Level of Grandparental Investment

David Bishop
Luther College, Decorah, IA, USA

Synonyms

[Discriminative grandparental solicitude](#); [Grandparent investment](#); [Paternity uncertainty](#); [Preferential investment in more certain kin](#)

Definition

Any investment by grandparents that increases or contributes to a biological grandchild's survival and/or reproductive fitness at an opportunity cost to the grandparent.

Introduction

Human grandparents often invest heavily in their grandchildren. Enjoying a long post-reproductive period, human grandparents are afforded many

opportunities to direct time and resources to their grandchildren. Grandchildren who receive such an investment are relatively more likely to survive and reach reproductive maturity (Gibson and Mace 2005; Sear and Mace 2008). According to kin selection theory (Hamilton 1964), humans can increase their inclusive fitness *directly* through reproduction or *indirectly* by helping their genetic relatives. Since grandparents share (on average) 25% of their genes with their grandchildren (over and above the large proportion of genes that all individuals share), grandparents can boost their inclusive fitness by investing time, energy, and resources in their biological grandchildren. This investment can take many forms and may change over time. It can range from direct behavioral forms of investment (child care, gift giving, financial support, contact behavior) to the psychological (guidance, advice, settling disputes, sharing of knowledge, showing interest). Whatever form this investment takes, grandparental resources are limited and their allocation should be maximized (Euler and Michalski 2007). Psychological adaptations may have evolved to regulate this investment to maximize fitness benefits.

One of the most consistent findings across the grandparental investment literature is the ordered level of investment of the different grandparents. Maternal grandmothers are often observed to invest the most in their grandchildren and enjoy the closest relationships with their grandchildren. Maternal grandfathers are typically next, followed by paternal grandmothers, and, finally, by paternal grandfathers (Smith 1988; Laham et al. 2005; Euler and Michalski 2007; Coall and Hertwig 2010). This investment differential suggests that grandparental investment is highly discriminative. A number of theories have been proposed to account for this discriminative investment psychology.

Paternal Uncertainty

The role of paternity uncertainty in the psychology of discriminative grandparental investment was first discussed by Dawkins (1976). Because of concealed ovulation, internal fertilization, and

the possibility of female infidelity, human males face a key adaptive problem – they can never be completely certain of their paternity. Thus, human males may unknowingly invest in another male's offspring. In contrast to males, human females are completely certain of their maternity even if they do not know the identity of the father. For human grandparents, this relational uncertainty may be present in two generations of descendants. Because the paternal grandfather cannot be completely certain of his relationship with his son or his son's relationship with his children, he faces two degrees of paternity uncertainty. Consequently, it is predicted that he will calibrate his investment in grandchildren accordingly. The maternal grandmother, on the other hand, is completely certain of her relationship to her daughter and her daughter's relationship with her children. Since the maternal grandmother faces no relational uncertainty, it is predicted that she will invest the most in her grandchildren. The maternal grandfather and paternal grandmother each face one degree of relational uncertainty: consequently, they will invest an intermediate amount in their grandchildren. The selection pressures created by these differing degrees of relational uncertainty are hypothesized to have crafted psychological mechanisms that regulate investment in a discriminant fashion.

Support for the role of paternity uncertainty in the psychology of discriminative investment by grandparents has come from a number of studies using various proxies of investment. The ordered pattern of differential investment has been found in a German sample of adults using retrospective reports of early care (Euler and Weitzel 1996), in a large-scale Dutch study of contact frequencies (Pollet et al. 2006), in the contemporary contact behavior (and closeness ratings) of US college students when all four grandparents are living (Bishop et al. 2009) and in child care in 13 contemporary European countries (Danielsbacka et al. 2011). These studies are notable for the consistency of their findings. An exception to this pattern of investment was reported by Pashos (2000). In this study, adults from both Germany and Greece were asked to retrospectively report on the care each grandparent provided up to the

age of 7. The findings from the urban areas in both Germany and Greece were similar to the above studies; however, for rural Greeks, paternal grandparents were reported as providing more care than maternal grandparents. The author speculated that the close residential proximity with the paternal family may have an increased paternity certainty relative to the urban settings.

Sex-Specific Reproductive Strategies

Studies of grandparent investment often reveal that maternal grandfathers invest more in their grandchildren than paternal grandmothers despite the same presumptive level of relational uncertainty. Euler and Weitzel (1996) suggest that, in addition to paternity uncertainty, grandparent solicitude should also be influenced by the sex of the linking parent. The task of the grandparent is to aid one's child (the parent of the grandchild) in his or her reproductive strategy. Since the maternal strategy differs from the paternal, the behavior of the grandparent is thus conditioned by the reproductive strategy of the linking parent. Maternal grandfathers, supporting the high investment strategy of their daughters, should therefore invest more than paternal grandmothers. In a sample of German adults reporting retrospectively on how much each grandparent had cared for them up to the age of 7, Euler and Weitzel found that paternal grandmothers did provide less care than the maternal grandfathers. In this study, both the sex-specific reproductive strategy and paternity uncertainty were significant determinants of grandparental investment. As they note, this means that the typically solicitous grandmother may become a relatively remote grandmother and the typically remote grandfather may become a relatively caring grandfather – depending on their child's sex. However, the authors acknowledge that partnership (co-residence) may also explain the investment dynamics of couples: for example, maternal grandfathers may invest heavily because they are partnered to high-investing maternal grandmothers.

Preferential Investment in More Certain Kin

In the ordered solicitude relationship discussed thus far, maternal grandfathers are often found to invest more than paternal grandmothers. Since both types share only one uncertainty link, parental uncertainty alone does not predict a differential in investment. Laham et al. (2005) have hypothesized that these two intermediate grandparent types with one uncertain link each will show an investment differential only under certain circumstances. Maternal grandfathers may invest more in their grandchildren relative to paternal grandmothers because *some* paternal grandmothers will have genetically more certain outlets available to them. If cousins are available through the father's sisters, a paternal grandmother will also be a maternal grandmother – she will have investment outlets that are more certain than her investment outlets with her son. Consequently, she may invest in her daughter's children at the expense of her son's children. In contrast, a maternal grandfather will not have a more certain outlet for his investment even if cousins are available through the mother's sister. Thus, relative to paternal grandmothers, maternal grandfathers should invest more heavily in (and be closer to) their grandchildren. The “preferential investment hypothesis” predicts that this investment differential between maternal grandfathers and paternal grandmothers will only emerge when there are cousins through the father's sisters.

The preferential investment hypothesis has received some support. In a sample of Australian psychology students, Laham et al. (2005) had grandchildren retrospectively rate their emotional closeness to each of their biological grandparents (check this). As predicted, maternal grandfathers were rated more highly than paternal grandmothers only when the paternal grandmother had grandchildren via her daughters. Danielsbacka et al. (2011) tested the preferential investment hypothesis in their large multinational study of child care. In this study grandparents self-reported the extent of provision of child care. Controlling for multiple potential confounds, their findings clearly supported the preferential investment hypothesis.

When women do not have more genetically certain investment outlets, the investment differential between paternal grandmothers and maternal grandfathers disappears. However, one test of the preferential investment hypothesis did not find the predicted effect. Bishop et al. (2009) asked college students with four living grandparents to indicate the frequencies of various contact behaviors received from or directed to each grandparent. In contrast to the above findings, grandchildren did not indicate more frequent contact with the maternal grandfather when more certain investment outlets were available to the paternal grandmother.

Reproductive Value

Not all individuals who share the same degree of genetic relatedness are equally valuable as investment outlets. As Hughes (1988) has noted, an individual's *reproductive value* (Fisher 1930) is another factor that may influence how many resources he or she receives. For human females, reproductive value (future reproductive potential) reaches its peak during the early twenties and declines thereafter. If a grandparent has the option of investing in a grandchild who has reached their peak reproductive window or in another grandchild, who is equally related but not yet in this reproductive window, the grandparents should favor the grandchild who has a higher probability of reproducing. Thus, the reproductive value of the grandchild should contribute to the calculus of differential grandparental solicitude. Consistent with this claim, Hughes (1988) has demonstrated that pubertal cohorts (those with the highest reproductive value) have the largest effect on inclusive fitness relative to any other subset of individuals in the population. Direct tests of this hypothesis with grandparents have not been conducted.

Conclusion

The fact that grandparents invest in their grandchildren to further their inclusive fitness and that the discriminative nature of this investment

may be driven by an adaptive calculus designed to solve domain-specific problems does not discount or diminish the important role that grandparents play in the lives of their grandchildren. Many grandparents sacrifice selflessly for their grandchildren and remain devoted even when separated from their grandchildren by great distances. Although the grandparent types often conform to an ordered level of investment in their grandchildren, it is important to remember that this is a differential that often cuts across high overall levels of investment. While many questions remain unanswered, this much is clear: a complete understanding of grandparent psychology cannot be adequately understood without consideration of the adaptive significance of grandparental investment.

Definition

Corporeal organisms are vehicles for the prorogation of genetic material, making organismic lifespan an expedient of reproductive output.

Introduction

Humans create machines of metal, plastic, ceramic, and wood that wear with age, eventually degrading and breaking down. It is then natural to think of aging cells, tissues, and organs, as wearing out and winding down as do sprockets, springs, and bearings (Hertler 2014). For all its intuitiveness, the analogy is misleading. Cells need not become exhausted and die. While this is the characteristic of complex, multicellular, sexually reproducing life, it is not invariably characteristic of simple, single-celled, asexually reproducing life (Hertler 2015). This was recognized as early as 1891 by August Weismann, who wrote, “Let us now consider how it happened that the multicellular animals and plants, which arose from unicellular forms of life came to lose this power of living forever” (Smith-Sonneborn 1987). Weismann continued on to qualify his understanding of lifespan as it relates to reproduction:

The immortality of unicellular organisms, and of the germ cells of the multicellular, is not absolute but potential; it is not that they must live forever; they can die – the greater number do in fact die – but a proportion lives on which is of one and the same substance with the others. Does not life, here as elsewhere, depend on metabolism – that is to say, a constant change of material? And what is it, then, which is immortal? Clearly not the substance, but only a definite form of activity. The protoplasm of the unicellular animals is of such chemical and molecular structure that the cycle which constitutes life returns ever to the same point and can always begin anew, so long as the necessary external conditions are forthcoming. This character it is which I have termed immortality. . . . (Weismann quoted by Kirkwood 1987, p. 209)

It required approximately seven decades and four discreet theoretical advances to answer the questions Weismann framed about the complex interplay between *life expectancy* and

reproduction. Together, the *pleiotropic view of senescence*, *The Selfish Gene*, the *disposable soma hypothesis*, and *life history theory* came to explain empirical realities, experimental findings, and biogeographical variation in life expectancy within and between species. In common, these four theories successfully explained lifespan precisely because they studied it in conjunction with reproduction.

The Pleiotropic View of Senescence

Successively, R. A. Fisher (1930), J. B. S. Haldane (1941), P. B. Medawar (1946), and G. C. Williams (1957) progressed toward the first convincing evolutionary explanation of senescence. As described by Hirsh (1987, p. 76), Medawar (1952) provided an analogical experiment for what is a pleiotropic view of senescence. Medawar envisioned 1000 test tubes, 10% of which shattered monthly by random accident and were subsequently replaced. Over time, applying this rule resulted in a population of test tubes that were predictably skewed, with test tubes less than a month old being more common than those a month old, and those a month old being more common than those 2 months old, and so on. It was at this point that Medawar introduced a proxy for senescence by appointing some specific older age at which test tubes would break, not by random accident but by intrinsic shortcoming. The results showed that, if the imposed senescence date was sufficiently late, it would have minimal effect, because, at that point, most of the test tubes would have been already broken through random accident. Lastly, and most importantly, Medawar found that the small cost of test tube senescence for the old could be countered, and even reversed, by a small advantage of test tube replacement for the young (Hirsch 1987). A fundamental transition had been made. Limited life expectancy was perhaps a reproductive strategy that outcompeted its opposite. Dying was not compulsory but competitive. Williams (1957) cited Weismann’s contributions while also critiquing them in his *Pleiotropy, Natural Selection, and the Evolution of Senescence*. With

this culminating publication came a mature theory of senescence that transcended intuitive, but unworkable, views of organisms as machines subject to wearing out and winding down. *Pleiotropy*, specifically, *antagonistic pleiotropy*, is where a gene encodes for a trait that is not decidedly detrimental or beneficial but double-edged. Each instance of antagonistic pleiotropy confers one trait with two repercussions, one that depresses fitness and one that enhances fitness. The fitness enhancing effects do not always exceed and overcome the fitness depressing effects, though by definition, such is the case for those pleiotropic mutations that persist with any frequency within populations. As can be seen, Medawar's test tube experiment was a model of antagonistic pleiotropy because late senescence was overcome by early proliferation.

The Selfish Gene

In theory, an automobile can run in perpetuity; it has no definite expiration date. When the car is new, it requires very little maintenance, generally only oil changes. After about 40,000 or 50,000 miles, slightly more costly service is required, such as new tires and brake pads. Another 30,000 miles more, the car is apt to need rotors, for instance, but by this time, very possibly an essential part has malfunctioned and is in need of replacement or repair. Entering into six-figure mileage will not require a six-figure salary, but it will come with still more costly repairs. Transition to what is unequivocally considered a high-mileage car is the point beyond which major repairs, including transmission rebuilds and engine replacements, become common. When an engine or transmission does fail on a high-mileage car, the driver often chooses to buy another car, and this is often a rational choice because the cost of such repairs will rival, and then exceed, the cost of replacement. Still, it is necessary to recognize that this is a rational turning point in a decision-making process, *not* a necessary decision. One can replace the engine and later, the transmission as well, and go on investing in the high-mileage car with no necessary end point. If the driver is

willing to weld cracks in the chassis, replace steering linkages, bond body damage, and the like, that same first car, becoming like Theseus' ship, can be theoretically driven for the duration. Life is very much like the above-described analogy of *The Selfish Gene* (Dawkins 1976). Adding another blow to the pride of person, in this analogy the organism is the car, and the gene is the driver who jumps from car to car. Dawkins' great insight was to exchange the organism for the gene as the unit of selection. From here, it is not hard to see why bodies are successively replaced. With oxidation, free radicals, and the cellular mutiny that is cancer, organisms in a sense do wear out just like cars, but also like cars, they can be theoretically maintained given sufficient investment. With this in mind, one can see that, with cars, there is some point at which a new car will more cheaply transport the driver; just as with organisms, there is some point at which a new organism will more efficiently propagate the genes. As the driver is economically compelled to trade in his high-mileage vehicle for a new one, the organism is evolutionarily compelled to cease investing in his body and channel efforts toward reproduction and the creation of a new organism. This gene-centric level of selection then clarified the implicit orientation away from the organism and toward the lineage that was contained within the antagonistic pleiotropy view of senescence.

The Disposable Soma

The Disposable Soma, a theory developed by Kirkwood (1977), came to incorporate aspects of August Weismann's work, emphasizing its distinction between the soma and germline, the ideas of Medawar et al. with its distinction between reproductive and post-reproductive life, and Dawkins' reorientation from the organism to the gene as the unit of selection. Like the car in the analogy above, or a disposable piece of cutlery, after the propagating function of the body is finished, so evolution is finished with the body. Consistent with a gene's eye view of selection and the understanding that survival is subordinated to reproduction, the soma is not an end unto itself

but a means to an end. Consistent with antagonistic pleiotropy, energetic saving came from attenuating somatic investment, thus allowing for the bodily deterioration known as aging. Consistent with Weismann and his barrier between soma and germline, the disposable soma hypothesis specified that somatic cells were allowed to senesce, germ cells were not. Sperm cells were constantly cycled, being purged and regenerated. Alternatively, egg cells, though present at birth, were subjected to oocyte atresia, which created an evolutionary process prior to conception, thereby barring mutated eggs from becoming implanted embryos. Yet, the disposable soma hypothesis served more than an integrative function; it pressed the concept of trade-offs to its logical conclusion. Here was the explicit recognition of finite resources being strategically divided between somatic maintenance and reproductive effort. The evolutionary optimum was specified to fall at the convergence of fecundity and somatic maintenance given a particular rate of survivorship.

Life History Theory

As with the antagonistic pleiotropy theory of aging, *life history theory* was developed successively by multiple researchers, with MacArthur and Wilson, Dobzhansky, Pianka, Roff, Charnov, Stearns, Harvey and Clutton-Brock, Rushton, and Figueredo among those making seminal contributions. But unlike antagonistic pleiotropy, or any other theory, life history theory was extraordinarily consilient because it subsumed lifespan and reproduction into a metatheory capable of contextualizing intelligence and personality, attachment and development, and risk-taking and restraint. Even when restricted to the biodemographic variables upon which life history theory was established (Wolf and Figueredo 2011), one can see its range: (1) size at birth; (2) growth pattern; (3) age and size at maturity; (4) number, size, and sex ratio of offspring; (5) age- and size-specific reproductive investments; (6) age- and size-specific mortality schedules; and (7) length of life. While wide ranging, these seven sets of variables can be reduced to

lifespan on one hand, and reproduction on the other, with all else being developmental markers tracking the trade-off between the two. As with the disposable soma hypothesis, life history theory described trade-offs between somatic and reproductive effort, but it did so in a more nuanced manner, which specified the overarching evolutionary development by which one or the other was emphasized. Moreover, within the context of life history theory, the importance of survivorship and mortality became fully apparent. Mortality regime was delineated into extrinsic, threats that could neither be predicted nor controlled, and intrinsic, threats that could be both predicted and controlled. As mortality threats became more extrinsic, life history speed quickened, resulting in the lower somatic effort and higher reproductive effort of a mouse, hare, or shrew, with their short lives and large broods. More than this, life history theory provided a framework by which the interaction between lifespan and reproduction could be more mechanistically understood. High predation, disease, or other hallmarks of extrinsic mortality that could neither be predicted nor controlled resulted in a more disposable soma with short lifespans and rapid aging, but the same evolutionary pressures also necessitated a congruent reproductive strategy replete with many young, produced early, and provided with little or no investment. Where mortality pressures precluded the development of long-lived individuals, it also precluded the development of small broods, enculturation, a long juvenile period, excessive maternal dependency, or large inter-birth intervals.

Experimental and Empirical Validation

These theories of lifespan and reproduction were not separated by a great deal of time, and furthermore developed in parallel, sometimes specifically referencing one another. It is beyond the scope of this entry to trace the precise contributions of each theory, the precedence of ideas, or the nature of their interrelations. Suffice it to say that all four theories, rather than replacing one another, accreted productively, with the end result

being a powerful understanding of lifespan and its relation to reproduction. Jointly, these theories explain a mass of empirically observable facts about the natural world (Wolf and Weissing 2012).

The idea of finite bioenergetic resources being traded off between somatic effort and reproductive effort, so central to the disposable soma and life history theory, is supported by the increased longevity resulting from castration observed in animals and humans (Min et al. 2012). Bioenergetics budgeting is similarly observed in instances of genomic imprinting, wherein resources imparted during gestation are a middle ground between the maternal pull against resource depletion and the paternal push for resource extraction (Burt and Trivers 2006). Though the less than monogamous male maximizes his fitness to the detriment of his mate, the female can only maximize the fitness of her offspring to the detriment of herself (van Noordwijk 2012, p. 322). Still further, Medawar's test tube analogy can be seen conforming to the empirical reality of prostate cancer and breast cancer. Both are deadly cancers of generative organs, both are frequent, and both most commonly afflict the post-reproductive. Like other lethal mutations that persist in the population (Rauser et al. 2009), prostate and breast cancer are often diagnosed in one's 1950s, 1960s, or 1970s after mating, weaning, and rearing. So there then is one of Medawar's conditions met, an attenuated fitness disadvantage. Prostate and breast cancer also meet Medawar's second condition, in that they likely confer a compensatory reproductive advantage. Prostate discharge comprises approximately one-third of ejaculate volume, protecting sperm as they enter the acidic vagina resulting in sperm survival, fidelity of genetic material, and resultant fecundity. What the prostate is to conception, the breast is to completed fertility.

Experimental evidence also supports the validity of characterizing mortality regimes as either intrinsic or extrinsic as a function of predictability and controllability. *Drosophila* experiments conducted by Stearns altered mortality rates, making them more or less extrinsic, which had the effect of decreasing or increasing longevity in

the predicted direction (van Schaik and Isler 2012). Similarly, experimental manipulation of guppies showed that longevity waned and fecundity waxed as a function of augmenting extrinsic mortality (Rauser et al. 2009). Across several treatment conditions manipulating variables such as food availability and temperature, reproductive effort and survival were negatively correlated (Hirshfield 1980). Further still, a population of asymmetrically fissile bacteria exposed to amplified extrinsic mortality were invaded by a highly fecund but rapidly aging morph (Rauser et al. 2009). Lastly, amphibian life histories respond to intensive parasite pressure, a salient form of extrinsic mortality, across markers of life expectancy and reproduction. With high parasite load, the pace of life quickened resulting in amphibians that spent less time growing and living and instead showed more rapid intergenerational turnover (Johnson et al. 2012).

Together, theories of aging also explain variation in life expectancy and reproduction as they are distributed biogeographically. As Gurven notes, low extrinsic mortality, and thus extreme longevity, is found in those desert, polar, or sub-alpine biomes that impose predictably harsh conditions, but which are relatively free of parasitism, predation, and other forms of biotic competition that become extrinsic sources of mortality for so many organisms. Consequently, one can observe long life expectancy and low reproductive effort among Siberian *Actinobacteria*, Antarctic plant species, and many desert succulents. Estuaries, rainforests, and reefs, on the other hand, teem with life. These are generous climatic zones where organisms compete intensively, parasitizing and preying on one another in a manner than can rarely be both predicted and controlled. The evidence for the above-described relationship is reproduced when observing stable micro-niches with low extrinsic mortality, even as they are contained within a larger ecology with high extrinsic mortality. Consequently, one can observe long life expectancy and low reproductive effort among Quahog clams, cave salamanders, and arboreal primates (Hertler 2017).

Beyond explaining variation in life expectancy and reproduction as they occur across species,

these theories also explain variation in life expectancy and reproduction as they occur within species. For example, the four theoretical advances herein described explain mean intrapopulation biogeographical variation in longevity among humans, carefully catalogued by the World Bank (<http://data.worldbank.org/indicator/SP.DYN.LE00.IN>), Central Intelligence Agency (<https://www.cia.gov/library/PUBLICATIONS/the-world-factbook/rankorder/2102rank.html>), and the World Health Organization (http://www.who.int/gho/mortality_burden_disease/life_tables/en/). Looking at the Central Intelligence Agency data set, for instance, shows clear biogeographic trends, with only Afghanistan intruding upon an African monopoly of truncated lifespan. Lifespan among the bottom 36 countries, 35 of which are in Africa, shows mean lifespans of around 55 years. In turn, the top 36 countries reporting mean lifespans of 80 or above contain 5 Asian countries with the remainder being comprised almost exclusively of European countries, their former colonies, or current dependencies. Though the reality of such disparities is irrefutable, explanations are various. War, poverty, disease, and political regime have alternatively been emphasized. The 12-year lifespan discrepancy favoring South Korea over North Korea, and the diminishing gap between what were formerly East and West Germany, validates such situational factors. On the other hand, longevity differentials persist in mixed-raced countries, recapitulating patterns found in the countries of origin, even while attenuating them. Supportive of the theories herein reviewed, these biogeographic patterns in lifespan are paralleled by biogeographic patterns in reproductive effort. According to United Nations data, unintended pregnancies are lowest within Asian and European countries and highest in African countries (Singh et al. 2010). Still further, those of African as opposed to European or Asian ancestry have sex more often before and after marriage. The same racial relationship holds for skeletal muscle, testosterone, combined testes weight, sperm production, secondary sexual characteristics, number of partners, and sexually transmitted diseases (Hertler 2015). Being a mixed-race society containing the extremes of the cross-national

lifespan continuum, the United States provides context. Along with Caucasians having longer lifespans than African Americans, African Americans reach menarche significantly earlier (<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4137967/>) and had an earlier mean age of sexual debut (<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3064497/>).

Conclusion

Though they have previously been studied in isolation, there now exists an empirically and experimentally supported theoretical framework wedding life expectancy to reproduction. These theories suggest that gene frequency is all that matter. With genes being emphasized above, organisms come to the realization that lifespan is simply an optimized time for genes to reside in a single organism, whereas reproduction signifies the point at which that optimum has been reached. Prior to these theories, it was as if a relay race was being watched, but not for so long that the baton was seen passing from runner to runner. With these theories, one can recognize the relay race for what it is and so focus on the baton rather than the runner.

Life Expectancy in Hunter-Gatherers

Brea McCauley

Simon Fraser University, Burnaby, BC, Canada

Synonyms

[Hunter-gatherer lifespan](#); [Traditional life-expectancy](#)

Definition

The average period an individual may expect to live among nomadic peoples who rely primarily on hunting, fishing, and harvesting wild foods.

Introduction

Hunter-gatherers do not experience short, nasty, and brutish lives as some earlier scholars have suggested (Vallois 1961). Instead, there appears to be a characteristic life span for *Homo sapiens*, in that on average, human bodies function well for about seven decades. These seven decades start with high infant mortality rates that rapidly decline through childhood, followed by a period in which mortality remains essentially the same to about 40 years. After this period, mortality rates rise steadily until around 70 years of age (Gurven and Kaplan 2007). Of course, mortality rates differ geographically and temporally, especially in the risks of violent deaths and disease. However, these differences are minimal when compared on

a global scale, and the mortality profiles of modern hunter-gatherers living in vastly different environments are remarkably similar.

Specifics of Hunter-Gatherer Lifespan

We know specific details about modern hunter-gatherer lifespan from a few well-studied groups: the !Kung, Aché, Agta, Hadza, and Hiwi (Gurven and Kaplan 2007). Work on these groups show that approximately 60% of hunter-gatherer children live to age 15. Of those who reach 15, around 60–80% of them will live to age 45. If an individual lives to age 45, then on average they will live for approximately two more decades. However, not all modern hunter-gatherer groups show the exact same lifespan profiles. The average life expectancy at birth among these groups varies from 21 to 37 years, and the proportion of individuals living to 45 years old varies between 26% and 43% of the population. These individuals who live to age 45 then have a continued life expectancy between 14 and 26 years.

The generally low life expectancy at birth among modern hunter-gatherers is due to their very high infant mortality rates, which pulls down their average life expectancy significantly. Compared to the United States, infant mortality is over 30 times greater among modern hunter-gatherers, and early child mortality is over 100 times greater (Zopf 1992; Hill et al. 2007). Even late childhood mortality is about 80 times greater among modern hunter-gatherers. Not until the late teens does the relationship start to even out, with over a ten times difference in mortality. This difference then continues to decline until it reaches age 70, where mortality among modern hunter-gatherers is only three times greater than individuals of the same age living in the United States (Gurven and Kaplan 2007).

Does Life Expectancy Among Hunter-Gatherers Represent Humans' Evolved Lifespan?

Given that the average human lifespan estimate was obtained from modern hunter-gatherer

populations, does it represent the evolutionary history of our species, or is it simply the result of modern civilization impacting these groups (Washburn 1981)? Comparative studies predict a human lifespan of 66–78 years from regressions of lifespan on brain and body weight (Hammer and Foley 1996). Converted to average adult lifespan, these results overlap with the observed lifespan from contemporary populations. Similarly, a reestimation of several Paleolithic mortality curves shows a Paleolithic life course pattern similar to those of modern hunter-gatherers (Konigsberg and Herrmann 2006). These types of comparative studies as well as studies on modern hunter-gatherer populations support the conclusion that the evolved average adult lifespan for *Homo sapiens* is around 70 years and thus individuals living long lives in both traditional societies and developed countries is not simply the result of modern medicine and hygiene (Blurton Jones et al. 2002).

There are a number of hypotheses as to why human lifespan is so long and includes a lengthy postreproductive period. Two notable examples are the “embodied capital model” (Kaplan et al. 2000) and the “grandmother hypothesis” (Hawkes et al. 1998). The “embodied capital model” proposes that learning the complexities of hunter-gatherer feeding environments requires a long time to master but provides high benefits later in life, thus favoring an extended life span. The “grandmother hypothesis” suggests that humans live to old age so that women can invest time and resources in their grandchildren.

Conclusion

Excepting outside forces such as violence and disease, hunter-gatherers can live to approximately 70 years of age. With this life expectancy, hunter-gatherers are not dissimilar to individuals living in developed countries. One major area of difference is the high infant mortality rate of hunter-gatherers, which pulls down their life expectancy at birth and influences their overall average lifespan. This pattern of life expectancy among hunter-gatherers is not only a consequence

of the impacts of modern civilization. Rather, humans appear to have an evolved lifespan of approximately seven decades that includes a lengthy postreproductive period.

[Etiology of psychopathology](#); [Life history theory](#)

Definition

Life history approaches understand psychopathology as long-term consequences of inevitable trade-offs in investment in reproductive (fast life history strategy) vs somatic (slow life history strategy) effort, interacting with the environment the individual finds themselves in.

Introduction

Psychopathology is characterized by harmful dysfunction, defined by harm to self or others and/or a failure of psychological mechanisms to serve the functions for which they were designed by natural selection. This entry will review evidence that has been collected relating life history strategy (LHS) to various psychopathologies. Early-life experience can lead to adopting a fast LHS, focusing on short-term gains, and consequent risk-taking, or a slow LHS in which resources are accrued and utilized more slowly and carefully. Evidence will be reviewed illustrating the link between these strategies and psychopathology, including a consideration of the

possible underlying mechanisms (hormones, for example), with respect to depression, anxiety, obsessive-compulsive disorders, schizotypal disorders, autism spectrum disorders, eating disorders, gambling, and other risk-taking behavior.

Life History and Psychopathology

Informed by our current understanding of the mechanisms involved in developmental plasticity, along with extensive nonhuman biological research and life history theory (Ellis and Del Giudice 2018; Ellis et al. 2009; Roff 1992; Stearns 1976), theories were developed as a means of explaining between (and later, within) species differences. Life history theory allows for behavioral and physiological adaptation across the life span, suggesting that environmental cues during key phases of development may set individuals on a path to utilize resources in a specific way, particularly with respect to reproductive, familial, economic, and social behaviors/strategies (Ellis and Del Giudice 2018; Ellis et al. 2009; Roff 1992; Stearns 1976). More specifically, life history theory proposes that organisms allocate time and energy differentially as a consequence of a variety of environmental cues and constraints and competing goals (e.g., fitness vs reproduction) (Figueredo et al. 2013; Roff 1992; Stearns 1976). In humans, research utilizing life history theory focuses on the cues and consequences of early life disadvantage in the early environment (Frankenhuis and de Weerth 2013; Nettle et al. 2013). LHT suggests that early-life cues predispose individuals to adopt either a “fast” or “slow” strategy (Del Giudice 2014a; Frankenhuis and de Weerth 2013; Nettle et al. 2013). More specifically, those who experience early-life adversity develop strategies focused on short-term goals and immediate gain (fast). Conversely, those whose early environments were stable, predictable, and abundant in resources adopt strategies, characterized by a more future-oriented, cautious perspective, where the long-term gain is prioritized over short term (slow). For example, with respect to attitudes to food, money, and mating strategies,

individuals at the fast end of the continuum might adopt more risky, opportunistic strategies (e.g., high (vs low) energy food, gambling, unprotected sex), whereas individuals at the “slow” end of the spectrum are more inclined to invest in long-term health and relationship goals (Del Giudice 2014a; Figueredo et al. 2014; Frankenhuis and de Weerth 2013).

The utilization of life history theory as a means of better understanding the nature, development, and outcomes of psychopathologies is a relatively new phenomenon (Del Giudice 2014a). However, an increasing body of literature, both within the evolutionary field and across the discipline, indicates that this perspective may provide a powerful framework informing research and intervention (Del Giudice 2014a; Ellis and Del Giudice 2018). As a framework, life history theory is useful in that it promotes more objective view of psychopathological behaviors (i.e., functional/adaptive vs deficit) (Ellis 2018), which in turn (and in line with traditional clinical approaches) promotes a strength-based approach to symptoms that can improve the efficacy of interventions (Del Giudice 2014a; Ellis 2018). The perspective also accounts for, and strengthens, the case for early intervention. The life history perspective has been useful in highlighting the importance of the function and ontogeny, as well as proximate and ultimate determinants of psychopathology. Psychopathology is characterized as harmful dysfunction, contingent on two conditions, harm to self or others and/or failure of psychological mechanisms to serve the functions for which they were designed by natural selection (Wakefield 1992). The term may refer to the study of, development of, manifestation of, or experience of psychological distress or mental illness.

While psychiatry and psychology frequently focus on descriptive frameworks as a means of diagnosis, the study of development (etiology) of psychopathologies, from genes to environment, is the focus of an increasing amount of research. Life history theory encompasses and promotes a gene/environment model, which encompasses current understanding of developmental plasticity, and incorporates other models (e.g., allostatic load

model, diathesis-stress model). This aligns with the National Institute for Mental Health, where research identifying mechanisms, gene/environment interactions is the focus of the RDoc perspective (Insel et al. 2010).

More specifically, there a great deal of focus on mechanism and ontogeny. The need for an integrative framework can be seen in the controversy around the diagnosis and treatment of mental health disorders (Del Giudice 2014a; Ward and Clack 2019). Current models are based on similarities between symptoms (DSM) and correlations between disorders (e.g., externalizing/internalizing) (Del Giudice 2014a). In this context, life history theory, with its broad, but connected, perspective, also encapsulating function and adaptation, has the potential to promote research and inform interventions. This is particularly the case given the extensive literature linking early-life environmental stress to the development of psychopathologies (Del Giudice 2014b; Pechtel and Pizzagalli 2011).

Life theory research can account for a range of candidate mechanisms in the development of psychopathology across a range of domains. These include developmental plasticity (Ellis and Del Giudice 2014), DNA methylation (Sumner et al. 2018; Vinkers et al. 2015), neuroendocrine system (HPA axis dysregulation, glucocorticoids, etc.), and neural changes, e.g., accelerated/delayed maturation in some areas of the brain (Tyborowska et al. 2018). It is also a useful framework for understanding the link between mechanism and behavioral manifestations (whether that is adaptive or maladaptive). For example, life history theory can explain the link between early environmental stress and delayed or reduced neurodevelopment (e.g., amygdala), leading to antisocial traits and then to psychopathy (Tyborowska et al. 2018). Similarly, life history theory is a useful framework for understanding the link between threat-related stress through telomere length and emotional processing which is linked to depression (Sumner et al. 2018).

The life history approach to psychopathology is well-aligned with the current identified need to reorganize diagnostic criteria along functional lines (Del Giudice 2014a). For example, the

range of symptoms/features of depressive disorders may be better understood in terms of different etiology within life history framework. In other words, for example, there are likely to be differences in symptoms (because of their potentially adaptive functions) between depression as a consequence of adverse life events in adulthood and as a consequence of childhood abuse (Del Giudice 2014a). Similarly, life history theories evolutionary basis provides potential explanations for sex differences in the etiology and presentation of psychopathologies. For example, it is well-established in the literature that the symptoms of depression vary between males and females. Symptoms of depression for males (e.g., aggression) vs females (e.g., self-harm) could be seen in terms of their potential costs – aggression (vs self-harm) may confer benefits or less cost for males (vs females) (Hurst and Kavanagh 2017). Where for females, physical aggression is likely to be costly, and emotional regulation through self-harming behaviors may be more functionally adaptive. Thus life history's functional approach may address limitations of our understanding of internalizing/externalizing disorders (Del Giudice 2014a).

While a number of specific models exist exploring psychopathology in terms of life history (e.g., pace of life, adaptive calibration, psychosocial acceleration), they overlap the sense that they identify the potential for the adaptive value of the psychopathological behaviors (Ellis 2018). This is a main advantage of life history models compared to other models of psychopathology. For example, while all models recognize the role of environmental stress, both historically and currently, life history models explicitly predict that behaviors may be maladaptive or adaptive and that this will depend on context (e.g., time).

Evidence for the utility of the application of life history (evolutionary perspective) in understanding the development of psychopathology can be found in nonhuman biology (Hill et al. 2019), psychiatric and psychological research (Del Giudice 2014a) (see, e.g., (Hurst and Kavanagh 2017; Sumner et al. 2018)), and adaptive (vs maladaptive) value of associated traits, e.g., risk-taking, aggression, early sexuality,

exploitative (fast), risk aversion, agreeableness, inhibition, and delayed sexuality (slow LHS) (Del Giudice 2014a). Psychopathologies implicated include depressive disorders (type dependent: fast/slow) (Del Giudice 2014a), anxiety (fast LHS) (Del Giudice 2014a), obsessive-compulsive disorders (slow LHS) (Del Giudice 2014a), schizotypal disorders (fast LHS) (Del Giudice 2014a), ASDs (slow LHS) (Del Giudice 2014a), and eating disorders (type dependent: dysregulated (fast), reactive (slow LHS)) (Del Giudice 2014a).

The proposed pathways (etiology) to psychopathology according to life history theory (Del Giudice 2014a; Hurst and Kavanagh 2017) include symptoms as strategies/adaptations. For example, psychopathy may be the consequence of traits that enable exploitation, whereas anxiety may be underpinned by adaptive traits evolved to enable survival in fast-changing environments. Another pathway implicates extreme expression/maladaptive levels of useful traits, for example, the pathway from disgust (a useful means of avoiding harmful toxins in the environment) to obsessive-compulsive disorder, the symptoms of which may be seen to be an extreme disgust response. A mismatch between behavior and environment at the individual level may also be utilized as a means of understanding the relationship between, for example, violence in the early environment to hypervigilance and anxiety in the adult environment (fast LHS). Similarly, the life history framework may explain the way life history leads to vulnerabilities. For example, risk-taking (a fast life history strategy) may involve drug use/unprotected sex, which in turn may lead to higher exposure to pathogens/toxins (e.g., infections/cannabis) which in turn increase likelihood of psychopathology (e.g., schizophrenia) (Del Giudice 2014a).

Life history focuses on the allocation of resources towards either reproductive or somatic effort. Increasing energy expenditure in one area necessarily results in a decrease to the other. Thus, an individual must be able to endure physiological and behavioral changes that ideally facilitate successful reproductive strategies. Many of these changes are regulated by the endocrine system, the internal collection of glands that regulate

homeostasis and growth. Responsible for changes in both physiological and behavioral processes through differentiation of hormone secretion, the endocrine system responds to cues in the external environment, by adjusting hormone production, as a means of best equipping the individual to its current environment.

While endocrine function changes throughout the life span, switch points in development have been implicated in the development of specific life history strategies (Del Giudice et al. 2009), where the external environment and the independent state of the organism interact to establish a strategy suited to the current environment. These switch points are established throughout puberty, where onset is arguably at either *adrenarche* (production of androgens by the adrenal glands) or *gonadarche* (production of androgens by the gonads). A key feature of these developmental switch points is the increase of sex-specific androgens, which may be the driving force between the development of specific life history strategies.

Sex-specific androgens are seen as the primary factor in the development of physical traits during puberty. In both human and nonhuman males, both natural variations in testosterone and manipulation of testosterone result in a switch in allocation of somatic effort (Muehlenbein and Bribiescas 2005). Evidence indicates that an increase in testosterone leads to a decrease in select immune functions, which, in terms of life history theory, suggests that increased reproductive effort is coordinated with a decrease in somatic effort.

Bribiescas (2001) theorizes that testosterone plays a role in driving the functional reproductive processes evident in both physiology and behavior. He also theorizes that allocation of skeletal tissue is indicative of a faster life history, the process of which is mediated by testosterone (Bribiescas 2001). This corresponds with evidence suggesting testosterone is associated with competition for mates (Ronay and von Hippel 2010). Further support for this notion can be found in evidence around the immunocompromising effects of testosterone in males, given this effect would be maladaptive for an individual that had more resources to allocate to somatic energy.

While life history emphasizes that reproduction is the ultimate end goal, hormonal output associated with this may have maladaptive effects, leading to the development of psychopathology. High levels of testosterone are associated with aggressive behavior. While aggressive behavior could be advantageous in intrasexual competition for mates, the reduction of such behavior in human societies means violent behavior may be maladaptive. While the association exists between testosterone and aggressive behavior, this may not be due to testosterone itself. Rather males have an increase in testosterone in the presence of competition, which in turn influences aggressive behavior (Archer 2006). This uptake in testosterone has been linked with varying antisocial behaviors (e.g., assaults, use of explicit drugs, etc.) but is likely mediated by individual environment.

While fast life history strategies are typically more likely to include maladaptive behaviors (at least in the long term), slow life history strategies can also lead to psychopathology. While fast maladaptive behaviors are associated with health risks through externalizing behavior (e.g., violence, substance use), internal behavior functioning may be maladaptive as a consequence of lower exposure to circulating testosterone. Low-level testosterone is associated with depressive symptoms. A study by Granger et al. (2003) found that in adolescent males, higher anxiety-depressive symptoms in males were associated with lower levels of testosterone and smaller fluctuations of testosterone levels throughout a day of hormone testing. This highlights the possibility that over-allocation of energy to somatic effort could manifest as overprotection towards survival through anxiety-like symptoms. Despite this link between low levels of testosterone and depressive-like behavior, Del Giudice (2014a) argues that depressive symptoms can be indicative of either fast or slow life history.

The variation in sex-specific hormones and the integration of the endocrine system are illustrations of the usefulness of a life history theory framework in understanding psychopathology. Other hormones (e.g., insulin-like growth factor 1 (IGF-1), cortisol, estrogen, etc.) also interact

with testosterone and have their own life history-related functions, and together their action (and reaction) plays an important proximate role in implementing an individual's life history strategy and so will likely also play a role in the development of psychopathologies. While distinct links between testosterone and male life history have been made, there are very likely to be important links between female hormone functioning and life history, topics for future investigation.

Conclusion

There are ostensibly a number of competing models of the etiology of psychopathology, each of which has some empirical support and each of which shares some features with life history theory, but, as illustrated above, a life history approach has the promise of bringing all such models together. A common, but nonfunctional, approach to psychopathology is the **stress-diathesis model**. The central hypothesis is that stressful environment/life experiences interact with genetic/behavioral/physiological predisposition/vulnerability leading ultimately to psychopathology (Albott et al. 2018; Ellis et al. 2011). There is a vast literature broadly supporting this model, but it necessarily characterizes psychopathology as maladaptive, which, as explained above, may underestimate the complexity of the relationship between early environment and behavioral outcomes. A second, broad approach to psychopathology can be described as **cognitive models**. In such schemes, emotional dysregulation produced by environmental challenges (like stress) results in maladaptive strategies of emotion management in some individuals (like excessive rumination), and that can result in psychopathology (like depression or anxiety) (Dvir et al. 2014; Peters et al. 2018; Sumner et al. 2018). Again, there is ample evidence to support the idea that individual differences in dealing with life's challenges explain some of the variance in psychopathological symptomology, but these models, in isolation, leave unanswered the question of the origin of the individual differences. **Allostatic load** models of psychopathology

propose that increased wear and tear due to the physiological costs of stress lead to a range of health issues including psychopathologies (Ellis and Del Giudice 2018; Del Giudice 2014a; Kotov et al. 2017; Ward and Clack 2019). The fundamental idea of such approaches is that dealing with stressors activates allostatic mechanisms, in order to achieve homeostasis, but that repeated, or excessive, use of these mechanisms “overloads” the system and results in a range of pathologies, some of which manifest psychologically.

One of the main strengths of life history theory, as an approach to psychopathology, is that it brings all of these other approaches together into a unifying, functional framework that provides a deeper understanding of the nature of the psychopathologies and offers the hope of an integrated approach to treatment and (perhaps especially) to prevention.

Synonyms

Fast and slow strategies; Life history tradeoffs;
R and K strategies

Definition

Life history theory posits organisms face tradeoffs in how they allocate resources to reproduction, parenting, and growth. These patterns of resource allocation can be classified more broadly into life history strategies, which vary on a continuum from fast to slow. These distinctions can be applied to describe within species and between species differences. Slow strategies are marked by increased investment in growth, a delay in reproductive investment, and increased investment in parenting. In contrast, fast strategies are marked by early investment in reproduction at a cost of growth and a reduced investment in parenting in favor of further reproduction.

Introduction

Life History Strategies

Life history theory (LHT) is grounded in a simple premise – resources are limited and thus organisms face tradeoffs in how they “decide” to allocate those resources to growth, health maintenance, and various forms of behavior. These choices involve seeking a benefit on one trait that incurs a cost on another trait. In essence, LHT addresses how an individual’s life-stage, state of health, and local ecology determine that individual’s range of possible allocation strategies, all of which vary in their fitness maximizing potential (Del Giudice et al. 2015). Whereas somatic investment involves growing and maintaining the physical body and mind, reproductive and parental investment involve competition with same-sex individuals, courtship, procreation, the rearing of offspring, and so on. Tradeoffs along these dimensions can further be characterized by another set of key investment conflicts: (1) current versus future reproduction, (2) quantity versus quality of offspring, and (3) mating versus parenting effort. For example, an individual could spend energy on producing a relatively large number of children but limit the amount of parental care devoted to those children, or instead that individual could produce a small number of children and bestow extensive parental care to the growth and development of those children. Importantly, there is no one absolute correct response to these tradeoff conflicts. Whether a given decision is adaptive depends on what the decision maker’s environment affords. Investing in child quality may produce better long-term outcomes for that child, but in a particularly harsh and unforgiving environment, a given child might not survive over the long term. In such conditions, having many children may increase the chances that at least one child survives into adulthood to reproduce himself or herself. Therefore, the particular strategy most functional for an individual depends on the local environment (Del Giudice et al. 2015).

Researchers classify typical response patterns to such tradeoffs as life history strategies, which vary along a continuum from slow to fast.

Between and within species, slower strategies – marked by slower growth and later reproduction – correlate with longer lifespans, later maturation, fewer offspring, lower overall mating effort, and higher parenting effort. In contrast, faster strategies – marked by faster growth and earlier reproduction – correlate with shorter lifespans, early maturation, more offspring, higher mating effort, and lower parenting effort. Researchers have identified a number of correlates of life history strategies within humans, several of which are shown in Table 1. Individual differences in life history strategies have important consequences for our understanding of a variety of human cognitions and behaviors. Below, the origins of life history strategies are explained, and then the effects of slow/fast strategies on a number of important psychological domains are detailed.

Ecological Conditions

Investigations into the particular life history strategies that individuals follow indicate that allocation “decisions” are primarily a function of the

Life History Strategies, Table 1. Correlates of fast and slow life history strategies

Faster strategy		Slower strategy
	Physiology	
Faster	Rating of development	Slower
Earlier	Onset of puberty	Later
Faster	Biological aging	Slower
	Mating	
Earlier	Sexual debut	Later
More	Sexual partners	Less
Casual	Relationships	Pair-bond
	Parenting	
Earlier	Age of reproduction	Later
Higher	Number of offspring	Lower
Lower	Investment in offspring	Higher
	Reward orientation	
Short	Time horizon	Long
High	Impulsivity	Low
Take	Risk for reward	Avoid

Note. Table adapted from Griskevicius et al. (2013)

harshness and stability of the local ecology. Harshness refers to age-specific rates of morbidity-mortality in the environment (Ellis et al. 2009) and may be operationalized by, for example, parenting styles, childhood socioeconomic status (SES), or the extent of childhood illnesses (e.g., Belsky 2012; Simpson et al. 2012; Finch and Crimmins 2004). Unpredictability refers to the degree to which there is stochastic variability in the harshness of an environment across time. If an environment is unpredictable, it may not be optimal from a fitness standpoint to invest energy in long-term outcomes when one is unlikely to survive to benefit from that investment. Following this view, unpredictability has often been operationalized as parental change in residence, job, and cohabitation status (i.e., romantic partners moving in and out; Simpson et al. 2012; Szepeswol et al. 2015).

Whereas individuals who grow up in harsher, more unpredictable environments tend to develop faster strategies, children who grow up in more resource-abundant, supportive, and predictable environments tend to develop slower strategies. Moreover, this effect of the environment on the development of life history strategies appears specific to early childhood environments and experiences (Griskevicius et al. 2011; Belsky 2012; Simpson et al. 2012). For example, Simpson et al. (2012) found that an unpredictable family structure before age 6 influenced adult sexual activity and aggressive behavior more than the family structure after age 6. Additionally, research has identified unsupportive parenting and insecure attachments as mediating factors between environmental harshness/unpredictability and fast strategies in adulthood (e.g., Belsky et al. 2012; Szepeswol et al. 2015; Sung et al. 2016). Children may use cues to harshness and unpredictability in their early environments to forecast the extent and permanence of future resources and receive input from their parents that is either consistent or inconsistent with these cues.

Despite increasing amounts of research on the effects of early-childhood harshness and unpredictability environment on life history strategy development (e.g., Belsky et al. 2012), it is currently unclear under what conditions each factor contributes to specific dimensions of life history strategies. For instance, when harshness and

unpredictability are pitted against each other, harshness seems to be a stronger predictor of menarche (e.g., Sung et al. 2016); however, unpredictability appears to better predict number of sexual partners and criminal behavior (e.g., Szepeswol et al. 2015; Simpson et al. 2012). The differential effects of harshness and unpredictability may indicate that each factor is uniquely associated with specific outcomes.

Individual Differences in Environmental Sensitivity

When environments are highly variable over time or space, natural selection may favor developmental plasticity: biological mechanisms that can respond to cues in an individual's environment in order to "match" that person to the affordances of the environment to better maximize potential fitness. This plasticity can be expressed in at least two ways.

First, plasticity may be important for the initial development of one's life history strategy. Consider the following situations. In a relatively stable environment, or one in which cues to environmental conditions are unreliable and plasticity costly to maintain, selection may favor more fixed genotypes, "specialists" in a given allocation strategy. However, when the environment is variable and cues are both detectable and predictive of relevant social and physical features of the local environment, selection may favor individuals who are more "generalist" in their ability to calibrate their developmental trajectory to fit local conditions (Del Giudice et al. 2011). Given variable environments and the opportunity to change habitats, both specialist and generalist genotypes can exist together in a population. For instance, researchers examining this possibility studied the development of respiratory illnesses in 3–5-year-old children as a function of both their early rearing environments and individual differences in both cardiovascular and immune reactivity. Children with low reactivity – less plastic phenotypes – were no more likely to develop respiratory illnesses in high adversity settings compared to low adversity settings. However, highly reactive children – more plastic phenotypes – had the most

frequent instances of respiratory illness in high adversity settings, but they had the least frequent instances in low adversity settings (Boyce et al. 1995; Del Giudice et al. 2011). Individual differences in sensitivity to the environment can help explain why environmental variables (e.g., family environments, parent–child relationships) often have weak effects on developmental outcomes; effects tend to get stronger when individual differences in stress reactivity are taken into account. For example, Ellis et al. (2011) found that parent–child relationships uniquely predicted earlier puberty for children with heightened SNS/HPA activity, a measure of the stress response system (SRS) (Del Giudice et al. 2011).

Second, plasticity plays an important role in the proximate expression of life history strategies, even in adulthood. Sensitization models of life history suggest that childhood background may have relatively a minor influence on many of the behaviors and decisions adults make in relatively stable and benign environments, but when an environment appears threatening due to some cue, fast and slow patterns of behavior emerge (Griskevicius et al. 2011a, b; 2013). For example, in one set of studies, participants who grew up poor took more risks and discounted the future more than participants who grew up wealthy when presented with a news story about economic recessions, but there were no differences between these participants when the recession cue was absent (Griskevicius et al. 2013). In sum, the work conducted on life history strategies is broad: some studies find that early childhood levels of harshness and unpredictability predict adult outcomes such as risky sexual behavior and delinquency (e.g., Simpson et al. 2012; Belsky et al. 2012), and others demonstrate environmentally contingent responses to threat when cueing current mortality or resource scarcity (e.g., Griskevicius et al. 2011a, 2013).

Influences on Key Life History Domains

Life history strategies have been tied to many outcomes, including outcomes in clearly relevant domains such as physiological development, mating, and parenting. These outcomes also hold

strong implications for psychologically important concepts such as risk-taking, personality, and psychopathology. The following sections explore this research in more detail.

Somatic Development

As mentioned earlier, life history strategies entail trade-offs in investment within somatic, reproductive, and parenting domains. Fast strategists tend to invest less in somatic and parenting goals in favor of reproductive goals. This allocation of bodily resources encourages faster physiological development of sexual characteristics but impairs other forms of bodily growth and maintenance. Kuzawa and Bragg (2012) summarize a variety of studies that find a strong relationship between harsh early environments and impoverished physical characteristics, including (reduced) stature and (accelerated) aging. Such effects may be driven by particular aspects of the environment, including childhood nutrition, environmental stressors (e.g., poverty, authoritative school environments), and infection at childhood.

Much of the research done on aging emphasizes the progression of reproductive stages such as puberty (see Belsky 2012; Del Giudice et al. 2015 for reviews). Consistent with LHT, early childhood psychosocial stress seems to *accelerate* puberty. For instance, girls who were adopted at older ages and who therefore suffered more time in unfavorable orphanage conditions entered puberty more rapidly than earlier-adopted girls (Proos et al. 1991). Factors indexing environmental harshness and unpredictability also predict earlier age of menarche (i.e., first menses). For example, father absence and family conflict are associated with earlier puberty in females (Moffitt et al. 1992; see Belsky 2012 for review on studies on age of menarche). In men, some work has examined peak height velocity, the point at which males reach a maximum rate of growth. Men who were born small and who gained weight rapidly from birth to age 2 (a proxy for environmental unpredictability) experienced peak height velocity earlier (Karaolis-Danckert et al. 2009).

Based on LHT, a person's aging and dying progression should also be determined by how harsh their early environments are. This is because

an individual who is born into a harsh environment and therefore on a fast track may invest less in their personal survival or may just suffer more risk of dying sooner. There is indeed evidence that early life harshness is associated with increased old-age mortality. For instance, Finch and Crimmins (2004) found that in the USA and Sweden, childhood illnesses and nutrition deficits significantly predicted shortened lifespans. In the same vein, in an analysis of hunter-gatherers and forager-horticulturalists, higher infant mortality, infection rates, and violence were tied to a decrease in lifespan (Gurven and Kaplan 2007). Chisholm et al. (2005) went as far as to ask women who grew up in unpredictable environments to estimate their life expectancy; they indeed found that early life unpredictability reduced subjective life expectancy. Together, these findings provide evidence that early harsh and unpredictable environments accelerate maturation in favor of early reproduction, at the cost of more rapid aging and mortality.

Mating

Life history theory predicts that fast strategists should seek to reproduce earlier and at greater rates, implying a greater number of sexual partners and less stable relationships with those partners. Slow strategists, who invest more in embodied capital, should, in contrast, begin sex later in life, have fewer sexual partners, and have more lasting, pair-bonded relationships.

These ideas have been tested in several longitudinal datasets. In an analysis of the National Longitudinal Study of Adolescent Health (Add Health), a nationally representative longitudinal study spanning from seventh grade to young adulthood (ages 18–26), researchers found that environmental unpredictability (i.e., instances of lack of care/needs not being met, being seized by social services) in adolescence was associated with lower sexual restrictedness (e.g., more risky sexual behaviors and less frequent use of contraception; Brumbach et al. 2009). Concordantly, in an analysis of the Minnesota Longitudinal Study of Risk and Adaptation (MLSRA), a longitudinal study tracking approximately 165 individuals and their biological mothers from before birth to

middle adulthood, childhood exposure to harsh (i.e., low childhood SES) and unpredictable environments (e.g., multiple changes in employment, residence, cohabitation) interacted to forecast earlier sexual debut: those exposed to harsh yet *predictable* environments from age 0 to 5 had first sex *later* than average, and those exposed to harsh yet *unpredictable* environments had first sex *earlier* than average (Simpson et al. 2012). High levels of childhood unpredictability at age 0 to 5 (not age 6 to 16) also predicted more sexual partners by age 23. A separate analysis using the same variables measured instead at age 6 to 16 found no such effects.

In a separate study, Belsky et al. (2012) examined data from the NICHD Study of Early Child Care and Youth Development, a study of 1,300 children and their families from infancy to age 15. Here, harshness was operationalized as income-to-needs ratio from ages 0 to 5 (lower scores indicating fewer needs were met). Unpredictability was measured as in Simpson and colleagues' MLSRA project (Simpson et al. 2012). Mirroring Simpson and colleagues' findings, high levels of childhood unpredictability and high levels of harshness (i.e., a low income-to-needs ratio) predicted a larger number of sexual partners. This was serially mediated by maternal depressive symptoms and maternal sensitivity (i.e., responsiveness and care) at childhood. That is, harsh and unpredictable ecologies were associated with greater depressive symptoms; these, in turn, were associated with less sensitivity, and lowered maternal sensitivity led to more sexual partners as the child grew up.

Beyond mating behavior itself, the quality of romantic relationships may be influenced by particular life history strategies. Some work suggests that fast strategists tend to engage in less committed romantic relationships. This could reflect their own insecure attachment orientations which may lead to their having more, and more genetically varied, offspring (e.g., Del Giudice et al. 2015; Barber 1998). For instance, unstable parental relationships in childhood (indexed by larger numbers of stepsiblings) predicted lower college GPA as well as greater frequencies of low-commitment relationships, particularly for daughters (Barber

1998). For the daughters in this study, the effect of unstable parental bonds on lower GPAs was mediated by their orientation towards low-commitment relationships, illustrating the trade-off between investing in somatic capital (operationalized by GPA) vs. investing in current reproduction. In sum, life history strategies affect a range of mating-related outcomes, from specific partner preferences to relationship quality and longevity to sexual behavior.

Parenting

According to LHT, the adaptiveness of parenting investment is dependent on aspects of the local environment. Parenting refers to outcomes related to child rearing, but it also extends to earlier processes such as gamete production and the timing of births. The theory predicts that, relative to slow strategists, fast strategists should devote fewer embodied resources to creation of gametes, have children sooner, and spend less time and effort on rearing behavior. Consistent with this idea, multiple studies have demonstrated the link between indicators of high mortality and age at first birth (e.g., Chisholm et al. 2005). For instance, Nettle et al. (2011) found that experiencing many residential moves during childhood, low investment from parents, and maternal absence each independently reduced age of first birth by half a year. Another set of experimental studies showed that ecological threats to mortality can influence the motivation to reproduce. In these studies, Griskevicius et al. (2011a) primed participants with a mortality cue (reports about violent crime) and then assessed attitudes towards early reproduction. Participants who grew up in resource-scarce environments (i.e., fast strategists) responded to the mortality cue by becoming more open to having children earlier in life. These fast strategists were also more likely to choose starting a family over furthering their own education and careers. The opposite patterns emerged for people who grew up relatively financially well off (i.e., slow strategists).

Less work has been done examining the direct consequences of life history strategies on investment in child rearing (e.g., parenting styles). Overall, LHT predicts that early environmental

harshness and unpredictability should be associated with greater emotional distance and less engaged parenting. However, Parental Investment Theory (PIT; Trivers 1972) suggests sex-differences will exist in parenting outcomes. This latter theory predicts that the sex that incurs higher reproductive costs tends to focus relatively more on their mate's genetic quality and ability to provide consistent resources, elements useful for creating viable offspring. In contrast, the sex that invests less in parenting tends to invest more in mating effort. In humans, women carry most of the burden in caring for children and face higher bodily costs from reproduction (e.g., pregnancy). Thus, PIT predicts men are more likely than women to disengage as parents, thereby increasing their fitness by investing in other domains (e.g., other mating opportunities). In contrast, women may increase their total fertility primarily by having children at a younger age (Belsky 2012).

These hypotheses were tested in another analysis of the MSLRA, featuring 112 individuals (and their low-income mothers) tracked from birth to parenthood (Szepeswol et al. 2015). All individuals completed an interview at age 32 that assessed their general orientation towards parenting. Unpredictability from age 0 to 4 was operationalized by their parents' changes in employment, resident, and cohabitation status during that period. Men (but not women) who experienced early-life unpredictability had a less positive orientation to parenting at age 32 (i.e., lower emotional connectedness and parental involvement, and more hostile parenting). This was serially mediated by maternal supportive presence and insecure attachment, such that unpredictable childhood households had lower maternal supportiveness, leading to the development of insecure attachments, which then was negatively associated with a positive parenting orientation in adulthood and less supportive parenting behavior.

These above predictions and data were corroborated by online survey data from 435 parents, whose early childhood unpredictability was associated with more attachment anxiety and avoidance, which were negatively associated with men's parenting orientations (Szepeswol et al.,

2015). These studies demonstrate that early childhood unpredictability predicts expression of fast strategies through child rearing behavior.

Influences on Other Domains

Risk-Taking

Beyond the three broad domains of investment relevant to LHT (somatic, mating, and parenting domains), life history strategies have important implications for decision-making styles – namely, risk-taking and risk-tolerance. Fast strategies stem from a reaction to ecological cues signaling limited, unstable resources and shorter time horizons. This leads to a preference for immediate benefits and rewards relative to longer-term goals. As fast strategists are looking to jumpstart their reproduction and accumulate a greater number of children, their goal is to amass resources for the present. In contrast, slow strategists exhibit the opposite pattern, with an emphasis on personal survival as well as the survival of a few high-quality children, leading to risk-averse behavior and delay of gratification in favor of future payoffs.

These predicted patterns enjoy support from several studies. A large scale global study found that countries high in ecological harshness (e.g., high infant mortality, high homicide rate, low GDP, lower life expectancy, etc.) are populated by more people with risk-taking personalities who engage in more risk-taking behaviors (Mata et al. 2016). Relatedly, an analysis of the Add Health study mentioned earlier revealed that environmental unpredictability in adolescence (e.g., parents not tending to their children's basic needs and changing living situations) significantly predicted delinquency and impulsivity in young adults (Brumbach et al. 2009). Finally, an analysis of the MLSRA dataset revealed that people who experienced unpredictability (measured by changes in employment status, residence, cohabitation status) between ages 0 and 5 reported more delinquent and aggressive behaviors at age 23, such as lying/cheating, substance use, arguing, and being mean to others (Simpson et al. 2012).

Researchers have also explored risk-taking in experiments highlighting the contingent

expression of life history strategies. Griskevicius and colleagues found that priming people with either mortality or economic instability led people who grew up in poorer environments (i.e., fast strategists) to increase risk-taking in financial decisions marked by probabilistic and temporal differences. For instance, fast strategists preferred to take a chance on a gamble for \$20 rather than receiving a certain \$10, and they preferred smaller immediate rewards over larger later rewards (Griskevicius et al. 2011b, 2013). In contrast, people who grew up in wealthier environments (i.e., slow strategists) took fewer risks and preferred larger rewards later rather than smaller immediate rewards.

Life history strategies also play a role in risk management through bet-hedging. Bet-hedging can enhance long-term reproductive success at the cost of short-term fitness by decreasing variation in outcomes over time (Ellis et al. 2009). From a life history perspective, bet-hedging can help to manage risks in resource/financial decisions: LHT predicts fast strategists will rely more on diversified bet-hedging (i.e., diversifying investments into multiple choice options to reduce the risk of any single choice) and slow strategists will rely more on conservative bet-hedging (i.e., investing more in a smaller number of low-risk options). In related experiments, people who grew up in lower-SES households (i.e., fast strategists) tended to prefer diversification strategies when facing current mortality threat, including preferences for product variety and stock investments (White et al. 2013). In contrast, people who grew up in higher-SES environments and who were primed with mortality threat engaged in more conservative decision-making.

Personality

Variation in life history strategies may correspond with different patterns of stable personality traits. Fast strategies are typically associated with increased impulsivity, aggression, and sensation seeking but decreased sociality (Del Giudice et al. 2015). Borrowing from the Five Factor Model of personality, conscientiousness and agreeableness are often tied to reduced mortality, reduced mating effort, increased parental effort, and increased prosociality/cooperation, all

outcomes associated with slow strategies. Agreeableness, conscientiousness, and emotional stability all load onto the same factor called *alpha* or *stability*, a slow life history trait which negatively predicts impulsivity (DeYoung 2011). In contrast, some aspects of extraversion and openness to experience (e.g., dominance, sensation seeking, imagination) as well as neuroticism can be tied to outcomes associated with fast strategies: increased relationship instability, mortality, sexual partners, and antisocial behaviors (see Del Giudice et al. 2015 for a review).

Other, more pernicious types of personality traits are linked to fast strategies as well. For instance, dark triad traits (narcissism, psychopathy, and Machiavellianism) are associated with impulsivity and pursuit of immediate rewards (e.g., Jonason et al. 2012), characteristics of a fast strategy. Life history strategies themselves have even been construed as highly heritable personality traits (Figueredo et al. 2004). In this framework, the regulatory genes that produce strategic patterns of behavior would likely be conditionally expressed through interaction with environmental inputs, akin to the strategic plasticity discussed in earlier sections.

Psychopathology

Most theoretical work in developmental psychology suggests that negative experiences in early-childhood increase the risk of psychological distress and psychopathology in adolescence and adulthood. Recent evolutionary-developmental theorizing has incorporated LHT in order to, “address the organization of individual differences, the nature of environmental risk, the role of early stress, the nature of gene-environment interactions, and many other critical issues” (Del Giudice and Ellis 2014, p. 3) in our understanding of psychopathology. Del Giudice and Ellis (2014) outline four potential causal pathways from life history strategies to psychopathology. First, life history traits may be diagnosed as undesirable, pathological symptoms. For example, traits associated with psychopathy – low guilt, low empathy, high impulsivity – may increase fitness by increasing the ability to exploit others. Second, typically functional life history traits may express

themselves at maladaptive levels. It is possible that parents who are both high on some trait, but still within an adaptive and socially desirable range, may have a child who expresses the same trait at an extreme, maladaptive level. Third, strategies that are adaptive across individuals may prove maladaptive for a given individual. For example, aggressive behavior yields fitness benefits for males on average (e.g., increased access to mates), even though individual males can suffer devastating costs (e.g., dying in fights). Fourth, life history traits may increase risk for dysfunction. For example, schizotypal personality may increase verbal creativity and interest in short-term mating, thereby increasing fitness; however, when schizotypal personality is coupled with drug use, nutritional deficiencies, and infections, it can increase the risk of schizophrenia, thereby decreasing fitness (Del Giudice and Ellis 2014).

Broadly, factors that determine individual differences in life history strategies are expected to increase risk for some mental disorders and not others. Though psychopathologies associated with faster or slower strategies will overlap to some extent, faster strategies tend to be associated with subclasses of disorders characterized by impulsivity, disinhibition, and bizarre ideation; slower strategies, in contrast, tend to be associated with subclasses of disorders characterized by inhibition, over-control, and cognitive rigidity. For example, both fast and slow strategies are broadly associated with eating disorders and OCD, but faster strategies are associated with bulimia nervosa and OCD featuring autogenous (i.e., unevoked, internal) obsessions, and slower strategies are associated with anorexia nervosa and OCD featuring reactive (i.e., evoked from external stimuli) obsessions (Del Giudice and Ellis 2014). In general, faster life history strategies are associated with externalizing disorders, schizophrenia spectrum disorders, obsessive-compulsive disorder (OCD), bulimia nervosa, and depressive disorders; slower life history strategies are associated with obsessive-compulsive personality disorder (OCPD), OCD, autism spectrum disorders, the perfectionist and over-controlled subtypes of eating disorders, and depressive disorders (Del Giudice and Ellis 2014).

Conclusion

Life history theory is a powerful explanatory tool for organizing patterns of cognition and behavior. The strategies that emerge from differential investment in somatic, reproductive, and parenting outcomes are individually specific and often emerge through interaction between child and adult environmental conditions. Such strategies predict a wide range of outcomes, and many further topics in human psychology await placement within this important theoretical framework.

Synonyms

Biological ecology; Life history; Lifespan; Population ecology; Reproductive development

Definition

A theory based on biological evolution that explains variations in organisms' developmental and reproductive strategies in the context of environment pressures and available resources.

Introduction

The core premises of Darwinian evolution are survival and reproduction (Darwin 1859); and biological organisms need energy to achieve these goals. All life requires capturing and allocating energy; however, this energy is limited and comes at a cost – organisms cannot expend unlimited resources, maximizing all life domains simultaneously. Organisms must live within their restricted energy budgets, mandating tradeoffs to

ensure they do not allocate more resources to a particular domain than are available. Selection favors strategies for allocating resources on the basis that they result in the greatest evolutionary fitness for the organism, respective of their environmental constraints. Life history theory explains how organisms allocate energy to survival and reproduction to maximize their fitness; including passing on their genetic material. As a whole, life history theory serves as a framework to organize and understand species differences, sex differences, and individual differences, across a number of domains, including physical growth, sexual maturation, and sexual, social, and parental behaviors.

Human Ecology

Humans are biological organisms and therefore face the same adaptive problems of maximizing fitness through appropriate energy allocation as do all other organisms. It makes sense then, that theories of biological ecology (i.e., life history theory) can be applied to the human species. Approximately two decades ago, evolutionary psychologists started using life history theory to help explain human behavior in the context of reproductive strategies (e.g., MacDonald 1997), early childhood attachment (e.g., Chisholm 1996), and developmental trajectories (e.g., Ellis et al. 1999).

Researchers such as Jay Belsky and Bruce Ellis – who have their own separate entries in this section – have led the way integrating and reforming developmental psychology and development psychopathology with the inclusion of evolutionary psychology and life history theory into developmental models (e.g., Belsky et al. 2012; Ellis et al. 2011). Jay Belsky has been particularly influential in the areas of childhood development, including attachment processes and parent-child relationships (e.g., Belsky 1997; Belsky et al. 1991, 2012; Del Giudice and Belsky 2011). Bruce Ellis's most influential works include investigating the influence of father absence on the timing of pubertal development (e.g., Ellis and Essex 2007; Ellis and

Garber 2000; Ellis et al. 1999). Most contemporary postgraduate developmental psychology and developmental psychopathology books include and/or reference works from these two influential researchers and authors. As such, there are now hundreds of articles and numerous book chapters in the psychological literature using life history theory as a framework to help conceptualize and explain multiple human behaviors as fitness maximizing strategies. The focus of this literature spans from theoretical models of mental health and psychopathology through to explanations about variations in cognitive flexibility (i.e., ease at which we shift tasks).

Life history theory is a middle-level theory that requires the consideration of a number of underlying and associated concepts. These underlying concepts include organisms facing fundamental tradeoffs in the face of energy allocation, the costs and benefits of allocating energy to different domains, how different patterns of energy allocation result in within and across species variations, the influence of environmental factors, varying developmental trajectories, the role of genes (including epigenetics), and the resulting difficulties where there is a mismatch between behaviors and traits selected for an early environment that are no longer adaptive in a current environment.

Fundamental Tradeoffs

Optimal allocation of resources (i.e., energy) toward growth, development, reproduction, and survival varies across an organism's life course. At the most basic level, individuals must make fundamental tradeoffs between reproductive efforts and somatic efforts to enhance their inclusive fitness (Del Giudice et al. 2015). Individuals may prioritize somatic efforts, investing in tasks and traits that affect the age schedule of mortality. Somatic efforts include investing in growth, body maintenance, developmental activity, and survival. Alternatively, individuals may prioritize reproductive efforts over somatic efforts, investing in tasks and traits that affect the age schedule of fertility. These reproductive efforts can be divided into mating effort, parenting effort,

or nepotistic effort (Kaplan and Gangestad 2005); each with its own cost and benefit in terms of maximizing fitness.

The influence of life history traits on an individual's inclusive fitness are expressed through changes in fertility and/or mortality, with strategies that may be targeted at enhancing the longevity or fertility of offspring as well the parents' own fecundity and lifespan. The three main tradeoffs defined within life history theory are the present-future reproduction tradeoff, the quality versus quantity of offspring tradeoff, and the mating effort versus parenting effort tradeoff (Del Giudice et al. 2015). As selected traits contribute to an individual's evolutionary fitness, they involve substantial energy investment, involving both costs and benefits, engendering tradeoffs between different fitness components. That is, most of the selected traits have contrasting effects on fertility and mortality, or contrasting effects on the fitness components of offspring or oneself. For example, at the most basic level, the tradeoff between growth and reproduction means that if an individual is producing offspring, they are reducing their somatic growth and maintenance. On the other hand, allocating energy to somatic growth reduces fertility at younger ages, but subsequently increases fertility in later life; however, at the potential risk of not surviving long enough to reach sexual maturity and reproduce – especially if the organism's current environment has a high mortality risk from predation or lack of resources. If an individual chooses to engage in tasks to increase fecundity, such as increasing mating frequency, they may be simultaneously compromising survival due to a cost to their immune functioning. In the tradeoff between quality versus quantity of offspring, if an individual is allocating energy resources (e.g., time spent nurturing and feeding) to existing offspring, this will increase the quality of offspring, but will reduce an individual's own survival and/or fertility.

Cost-Benefit Analysis

Despite the concept of cost-benefit analysis being largely based in economic literature, this approach has revolutionized evolutionary theory, providing

a systematic way of understanding the effects of selection on inclusive fitness. This cost-benefit analysis and general economic approach to selection greatly expanded the theory of evolution by natural selection (inclusive fitness theory) and shaped evolutionary theory as we know it today. The economic approach resulted in the development of many notable middle-level evolutionary theories, including the theory of parental investment and sexual selection, the theory of parent-offspring conflict, and importantly life history theory (Buss 1995).

An example of the cost-benefit analysis includes the theory of parent-offspring conflict, which explores the disagreement between parent and offspring over the amount of parental investment (Trivers 1974). This theory highlights the cost-benefit analysis demonstrating that both domains (i.e., parental investment and own fertility) cannot be maximized simultaneously – greater energy in one domain results in less energetic resource for the other. Consider a mother feeding her newborn calf; the benefits to the offspring are large, increasing its chance of survival; however, the cost to the mother (measured by the reduction in her ability to produce additional offspring) is relatively small. As the offspring grows and develops, the benefits of being nursed decrease, but the cost to the mother continues to increase. At some point the cost of nursing will outweigh the benefits to the offspring, and if the mother continues to nurse, this will result in substantial costs to the mother's reproductive success. Much like the parent-offspring tradeoff, life history theory is largely concerned with strategic energy allocation, but specifically focuses on the timing of certain life events. Life history theory has increasingly subsumed the cost-benefit analysis into many domains within the theory itself (Kaplan and Gangestad 2005).

Environmental Harshness and Unpredictability

Environmental harshness describes the general physical strain and hardship experienced by an organism. Harsh environmental conditions reflect increased risk of morbidity and mortality, which

can be generated from a number of factors including resource scarcity, extreme climates, intrasexual competition, and threat of predation. Environmental unpredictability describes the variability in the outcomes of adaptive behaviors (Brumbach et al. 2009). That is, when environmental conditions vary in an unpredictable manner, the success of alternate adaptive strategies are arbitrary. Environmental unpredictability is a function of stochastic variation in environmental risk or harshness. As such, environmental harshness can be inconsistent over time and space and is therefore largely unavoidable. This environment unpredictability, especially at an early age, can lead an individual to experience stress reactions than can lead to changes in stress physiology and brain morphology (Ellis et al. 2013), thus ultimately affecting their developmental trajectory. In humans, these physiological changes include earlier pubertal development including the onset of menarche and secondary sex characteristics (i.e., breasts, pubic hair; see Ellis and Essex 2007).

Discounting of Future Returns

Present versus future orientation is a central feature of life history theory. Neither the willingness to delay gratification nor the tendency to discount future rewards in favor of short-term gains is considered inherently better, but the adaptiveness of these behaviors is dependent on the environment. Understanding the future versus present orientation directs attention back to the cost-benefit analysis. For example, in understanding impulsivity and risk-taking behavior in a present-orientated teenager, one must ask how this is benefiting the individual and at what cost. High-risk strategies that may include the expression of aggression, sensation seeking, and impulsivity may produce a number of short-term benefits, such as acquiring multiple sexual partners, acceptance into a certain clique, or early reproduction. However, these benefits are accompanied by long-term losses, such as compromised immune function, loss of job opportunities, or premature morbidity-mortality. In contrast,

future-orientated strategists may tradeoff short-term gains – that is, delaying immediate benefits of employment, marriage, or reproduction by pursuing years of tertiary education – in favor of long-term gains, such as achieving high social and economic status (Ellis et al. 2012). Often long-term planning and a future orientation are considered more socially desirable, whereas short-term planning and a present orientation are considered somewhat undesirable; however, the adaptiveness of these behaviors largely depends on an individual's environment.

Life History Strategies

The costs and benefits of prioritizing one factor over another in each of the fundamental tradeoffs (i.e., present-future reproduction, quality vs. quantity of offspring, mating effort vs. parenting effort) are in part a result of varying environmental pressures and, in turn, produce variation in behaviors in order to secure and allocate resources to the prioritized factor. For example, prioritizing somatic effort over reproductive effort in an unpredictable, harsh environment may result in death before reproduction has been achieved – the opposite of maximizing fitness and not an optimal energy allocation strategy. These differences in resource allocation in reaction to variations in environmental pressures in order to obtain an optimal fitness maximizing strategy are referred to as life history strategies.

Life history strategies can be thought of as functionally complex phenotypes that have resulted from the integration of physiological, morphological, and behavioral traits as an adaptive solution to environmental pressures and fundamental tradeoffs (Del Giudice et al. 2015). Species-level adaptive specializations lead to a number of different life history characteristics that fall along a fast-slow continuum. Furthermore, in response to these ecological variations, most organisms have the ability to slow down or speed up their life history strategy respective of their experienced environmental pressures. That is, life history strategies are not fixed and are subject to developmental adaptive plasticity.

The adaptive plasticity of life history strategies allows developing organisms, human and non-human, to assess their environment through contextual cues and adjust their allocation strategies accordingly (Del Giudice 2014). Adaptive plasticity follows the evolutionary rules of fitness maximizing, enabling organisms to adapt with the intention of increasing inclusive fitness in varying ecological conditions. These varying ecological conditions, which are often referred to within the evolutionary literature, include resource availability, extrinsic morbidity-mortality, and the predictability of environments (Kaplan and Gangestad 2005).

Resource availability within an environment sets the baseline for many developmental activities, including the development of life history strategies. Individuals who experience energetic stress are likely to shift to a slower life history strategy, which results in a more energy-preserving phenotype, characterized by slower growth and development, delayed sexual maturation, and low fecundity. On the other hand, the development of a fast life strategy relies on adequate bioenergetics resources to support rapid growth and development (Del Giudice 2014).

Furthermore, extrinsic morbidity-mortality – the external sources of death and disability – can largely determine an individual's strategy selection. Those who are exposed to higher levels of extrinsic morbidity-mortality, as indicated by environmental cues (e.g., exposure to violence, dangerous ecological conditions), are likely to adopt a faster life history strategy. Faster life history strategies in the context of high extrinsic morbidity-mortality function to reduce the risk of death or disability prior to reproducing by anticipating early maturation and the onset of sexual activity (Del Giudice 2014).

Life history theory and relevant research has shown that organisms are able to electively adjust their life history strategies in response to their environmental context throughout their development. That is, environmental harshness and unpredictability, including varying contextual cues of morbidity and mortality, are important in calibrating the development of life history strategies. For example, individuals who are exposed to environmental cues indicating higher risk of

juvenile mortality, such as increased violence or predation, are likely to select a fast life history strategy. That is, their contextual cues indicate that it would be beneficial to mature rapidly and reproduce in earlier stages of life, reducing the risk of mortality prior to producing offspring (Brumbach et al. 2009). In the case of unpredictable environments, the future is uncertain and therefore resources and energy that are invested in the future will likely be wasted. Rather, the individual should respond to these unpredictable conditions (e.g., erratic residential conditions, fluctuating economic circumstance, and changes in family structure) by selecting a faster life history strategy. Unpredictable environments may infer strategies that maximize reproduction in the face of difficult circumstance, at the risk of reduced life expectancy and decreased social and emotional functioning (Brumbach et al. 2009).

There is substantial empirical evidence exploring the real world application of these processes. For example, studies have demonstrated that greater environmental harshness and early exposure to ecological and social stress have been found to predict early onset of menarche in young girls (Ellis 2004). Furthermore, areas in which residents have a shorter life expectancies and higher risk of mortality (e.g., higher homicide rates) report younger median ages of women giving birth (Wilson and Daly 1997). It could be argued that this tendency to reproduce earlier is not due to a lack of education or family planning, but rather a strategic plan – to reduce the risk of dying prior to producing offspring. Additionally, individuals who are raised in unpredictable environments often have a bias toward strategies that involve producing a large number of offspring – a trait that is indicative of fast life history strategy (Mittal and Griskevicius 2014). By producing a larger number of offspring, there is an increased likelihood that at least some progeny will possess phenotypes that are compatible with the future environment, thus increasing chances of survival. Furthermore, experienced environmental harshness during adolescents, such as exposure to alcohol and substance use, daredevilry, violence, and risky sexual behavior, is predictive of social deviance and sexual promiscuity in adulthood

(Brumbach et al. 2009). Generally, individuals who are exposed to greater levels of environment harshness naturally select a fast life history strategy, allowing them to function logically and suitably, in the context of unsafe and unpredictable environments.

The predictability of an organism's environment may be deemed the most important factor in regulating the development of life history strategies. That is, the unpredictable variation in an organism's extrinsic morbidity-mortality over time and across variable ecological contexts largely impacts an organism's strategy selection. Those who are subject to unpredictable environments may be led to invest in behavioral adaptability and flexibility, enabling them to adapt to ecological variation (Del Giudice 2014). On the timeline of human development, variable and unpredictable contexts tend to infer faster life history strategies, thus imposing similar direction than that of environmental harshness. In contrast, safe and predictable environments are likely to result in the development of a slow life history strategy (Kaplan et al. 2000).

Individuals with faster life history strategies prioritize short-term gains, with little regard for long-term consequences. That is, as faster strategies are an adaptive response to harsh and unpredictable environments with future uncertainty, delayed rewards may never be realized. Conversely, in more stable and predictable environments, future orientation and slower strategies are considered adaptive – as the future is relatively predictable and the risk of mortality is lower, slow strategists are more likely to be long-term planners, who are willing to delay gratification and invest in future outcomes (Mittal and Griskevicius 2014).

Alongside environmental contributions to the development of life history strategies, genetic factors also have a role to play. Life history theory provides a contextualist view of the interaction of genetics and the environment, suggesting that these factors should coexist. Existing literature on human life history traits suggest moderate heritability with epigenetics – the alterations or even the repression of gene expression – playing a pivotal role in the transmission of environmental

effects on life history strategies across multiple generations (see Figueredo et al. 2004).

In short, fast life history strategies develop as a response to environments that are unstable and unpredictable and have greater risks of morbidity-mortality. Individuals with fast life history strategies prioritize reproductive efforts over somatic efforts, and mating efforts over parental investment – producing a large number of offspring rather than investing in the survival of existing offspring. Conversely, slow life history strategies often develop as a response to environments that are stable, predictable, and have fewer risks. These individuals produce fewer offspring, but largely invest in the quality and survival of existing progeny. Neither fast nor slow life strategies are fundamentally better – the benefits of each strategy are contingent on the individual's environment.

Prototypical r-/K-selected species. As a result of varying environmental pressures, some species are classified as r-selected or fast strategists and some as K-selected or slow strategists. So called r-selected species have a shorter lifespan, experience greater risk of mortality, and inhabit areas with varying population size. These offspring often have a small body size, experience rapid growth, and reach early sexual maturation. This shorter lifespan, higher risk of mortality, and tendency to reproduce earlier than most result in optimal discounts to future rewards, in favor of short-term gains. Conversely, K-selected or slow strategy species have a longer lifespan, experience fewer risks of mortality, and inhabit areas that have a constant or equilibrium population size. Offspring from K-selected species often have a larger body size, experience slower growth, and have a later sexual maturation. As a result of the longer lifespan and fewer environmental risks, K-selected species are more likely to be future-orientated, reproducing later in life. Therefore, organisms that are relying on future reproduction need to invest in somatic efforts to maximize their chances of remaining healthy and survival.

There are a number of exemplary species at each end of the fast-slow or r-K continuum. Rabbits are a good example of a typical r-selected animal species. On average they reach sexual

maturity within the first 6–8 months of their life, they have an extremely short gestation period, and they produce a large number of offspring within each litter. These r-selected traits are consistent across a number of small organisms (e.g., mouse, lemur, and frogs) demonstrating relatively short generation times and reaching sexual maturity quickly, as an adaptive response to their high predation rates. On the contrary, typical K-selected species, such as gorillas, elephants, sharks, and humans, have longer gestation times and a larger body size, reproduce later in life, and bear fewer offspring in comparison to faster strategy species (Campbell and Reece 2005). An extreme example of a K-selected species is the Greenland shark, an iconic species of the Arctic Sea, with the longest known lifespan of all vertebrates. Radiocarbon dating of a number of female Greenland sharks revealed that this species has a lifespan of at least 272 years, with the largest shark measured being approximately 392 ± 120 years old. These sharks grow and develop extremely slowly to a total of >500 cm and do not reach sexual maturity until approximately 156 years old (Nielsen et al. 2016).

Life history strategies vary across species, with the distinction between r- and K-selected, as well as within species that results in unique individual differences. Humans are a prime example, in that they differ from other species, but also show large amounts of within-species variation. Typically, compared to other species, humans have distinct life history traits including late onset of reproduction, an extended period of childhood vulnerability, and a longer lifespan. Despite humans being considered typical K-selected species, they also appear to vary along the fast-slow continuum as a response to different environmental contexts. For example, within humans, faster life strategies have been associated with having a more unrestricted socio-sexual orientation and engaging in more interpersonal and intimate partner violence (Figueredo et al. [under review](#)), increases in the ability to cognitively shift between tasks (Mittal et al. 2015), and increases in the tendency to consume more energy than required after a period of fasting (Hill et al. 2016).

Clinical Applications

Psychopathology. As life history strategies are the product of a number of genetic and environmental pressures, as well as constant tradeoffs between somatic and reproductive efforts, they may help to explain the development of so-called psychopathology in humans. That is, variations in life history strategies could be useful in determining individual differences in risk profiles for a range of mental disorders, with a life history theory perspective conceptualizing psychopathology as a reflection of fast and slow life history strategies. The general idea is that the way in which an individual configures their life history strategy may increase their risk of developing a specific disorder or cluster of disorders. For example, Del Giudice and colleagues (Del Giudice 2014; Del Giudice and Ellis 2014) propose four causal pathways for how life history strategies may contribute to the onset of mental illness: (1) adaptive life history traits could be considered as symptoms of psychopathology; (2) life history traits could be expressed at a maladaptive level; (3) certain adaptive strategies may result in individually maladaptive outcomes; and (4) life history traits may increase susceptibility to dysfunction (Del Giudice 2014, p. 269). Although these pathways are considered distinct, they are not exclusive and it is likely that they may co-occur in the etiology of a number of disorders.

A life history approach does not automatically assume that disorders are dysfunctional, but considers alternate explanations, including the possibility that some disorders may reflect adaptive traits and processes that enhance evolutionary fitness. A common example is that of aggression. While aggression is generally considered a socially undesirable behavior, it does provide some fitness benefits such as increased access to resources and mates through dominance over others. Aggression toward outgroup members can also serve to protect and enhance the survival of familial members and offspring. So, although these traits may be considered biologically adaptive, they will often involve substantial cost to an individual in the context of long-term health, wellbeing, and social acceptance in broader

society. Through the lens of life history theory, we may be able to determine the role and function of aggression in people in the context of their personal environmental pressures including their early and current environments. Therefore, a life history approach to psychopathology potentially provides insight into common underlying behaviors, traits, disorder comorbidity, and functional subtypes of specific disorders.

It is largely recognized that fast life history strategies predispose individuals to a number of disorders, whether this is as a result of maladaptive outcomes of life history traits or as an adaptive yet undesirable social behavior (Giosan and Wyka 2009; Hurst and Kavanagh 2016). Fast-spectrum disorders are those that show association with traits such as sensation seeking, risk-taking, disinhibition, and impulsivity, low levels of conscientiousness and agreeableness, and promiscuous sexuality, with early sexual maturation. There is reason to expect that slow strategies may also set the stage for the development of psychopathology with disorders characterized by risk aversion, behavioral inhibition, extremes of conscientiousness and agreeableness, restrained sexuality, and delayed sexual maturation (indicators of a slower life strategy) possibly leading to their own set of difficulties (e.g., obsessive-compulsive disorder, social anxiety disorder).

The classification of mental disorders conceptualized along the fast-slow continuum suggests a number of specific factors that may contribute to the onset of a disorder, irrelevant of their causal pathway, but despite clear associations, these traits may or may not play a causal role in the etiology of specific mental disorders. For example, positive schizotypal traits and autistic-like traits sit at opposite ends of the fast-slow continuum and may be diametrically associated with differences in life history strategies (see Del Giudice et al. 2014). From the life history perspective, schizotypy is considered an adaptive fast spectrum phenotype for its reproductive advantages of high mating efforts and reduced parental investment, whereas autistic-like traits are considered an adaptive slow spectrum phenotype characterized by reduced mating efforts and high parental investment. That is, traits related to

these disorder may be beneficial (greater mating or parental success) or they could be harmful (the expression of the disorder); dependent on genetic quality and the developmental context.

Personality disorders. Individual differences in personality are increasingly thought to serve an adaptive function, but it is less clear whether these same principles apply to extreme variants of personality – personality disorders. If personality were to reflect deleterious variations around a behavioral optimum, it would be expected that individuals with personality disorders would be the most maladapted; however, it is becoming commonly accepted that personality reflects adaptive alternate strategies, and therefore it should be considered that individuals with personality disorders may have the greatest evolutionary advantage (Vall et al. 2016). General criteria for personality disorders are largely focused on self-impairment and limited self-direction, traits that are marked by a present orientation and the opportunistic nature of a fast strategist. Traits such as impulsivity, risk-taking, disinhibition, and presentism are considered indicative of pathological self-impairment as per the personality disorder criteria; however, they could be thought of as behavioral dispositions that allow a person to logically adapt and suitably function in a novel and unpredictable environment. It has been suggested that the general criteria for personality disorders may combine individual differences in life history strategies and pathological dysfunction, reflecting a compilation of the failings of fast strategists (Hertler 2016). Further, despite the harm extreme personality traits may cause in everyday living, some extreme variants are not as disadvantageous to fitness as they may appear to be for social adaptation or wellbeing.

Although the framework is preliminary, the goal of the life history model is to map psychological disorders onto the fast-slow continuum to gain an understanding of how life history traits could be employed as a way to explore the fundamental underpinnings of psychopathology. The life history framework has been applied to a number of disorders, generating some promising results through the replication of the observed structure of psychiatric conditions (Del Giudice

2016). The life history model of psychopathology offers insight into the adaptive function of individual differences in life history traits, but also the differences in risk profiles for a number of psychological conditions. Through the exploration of etiological factors, including genetics and environmental context, the life history model offers an integrative approach to understanding mental illness.

The missing link. Current life history theoretical models of psychopathology (e.g., Del Giudice 2016) provide a solid foundation for conceptualizing mental health problems from an evolutionary perspective and explain the possible development of various disorders; however, the question still remains, why is it that only some individuals develop symptoms of psychopathology and others do not? There are people at each end of, and along, the life history strategy continuum that do not develop mental health problems. What discriminates between those who do and those who do not experience or develop mental health problems? One possible answer might be that of expectations. According to life history theory, organisms react to environmental contexts in preparation to most efficiently allocate energy in a fitness maximizing strategy. That is, there is an expectation that the environment is going to be a certain way and in which the organism has prepared itself *a priori*.

Expectations are about future possible events and are developed from prior experiences and knowledge and encompass both biological and psychological functions. At the basic biological level, examples include our circadian rhythm, with our biological clock expecting sunlight and darkness at certain times of the day. When we travel to the other side of the world, our biological clock's expectations are not met; hence, we experience jet lag until our clock can be recalibrated so that the expectations of the environment and the actual environment match. There is also evidence of this type of circadian expectancy in some plant species. For example, sunflowers have an expectation as to where the sun will rise and set, with the allocation of energy to cell growth unevenly distributed depending on the time of day, so that the sunflower is always facing the sun. That is,

overnight the cells on West side of the stalk on the sunflower grow more than the East side, causing the sunflower to lean toward the East first thing in the morning to catch the morning sun. During the day, the cells on the East side of the stalk of the sunflower grow faster than the West side allowing the plant to follow the sun and make the most of the important ultraviolet light (Atamian et al. 2016). Therefore, there is a biological expectation about the environment, resulting in an allocation of energy that best maximizes fitness.

In the psychological context, our schemas about the environment and relationships are developed at a young age and provide the blueprints for how to navigate our future relationships. If our early relationships are marked by interactions with fast strategists, we will develop schema and expectations about how to best navigate these relationships. Likewise, if we develop in a slower, more stable environment, our schema will likely reflect the best strategies to navigate those relationships with other slow strategists. Therefore differences in interpersonal skills and styles will be in part dependent on context of our early relationships. Indeed, there is evidence to support this notion that fast and slow strategists do indeed see the world differently and have developed different schemas with fast strategists having a more antagonistic social schema (Figueredo et al. [under review](#)) and more likely to engage in intimate partner violence (Barbaro and Shackelford 2016, March 27; Figueredo et al. [under review](#)).

Consider then if a person grew up in and were exposed to a harsh and unpredictable environment; they might reliably develop a fast life strategy. Alongside the prototypical fast life behaviors there would also be the development of cognitions or schema reflective of a harsh unpredictable environment, all of which would be adaptive in that environment. If the person then moved to a stable environment that would be more reflective of a slow strategist context, there would be a mismatch in behaviors and expectations between the fast strategist and the majority slow strategists that constitute the new environment. The fast strategist would bring with them expectations about the environment and interpersonal interactions that were no longer relevant. These might include

behaviors such as impulsivity, or cognitions such as a hostile attribution bias, that in the majority slow strategist environment would be pathologized as they fall out of the norm. Now, imagine this person went to university – a quintessential slow environment – where the environment rewards long-term planning discounting the immediate over the future. The behavioral and cognitive script for the fast strategist is not set up for that environment with greater expectations placed on the individual than are realistic for them to achieve. Failure to adapt and achieve these expectations would lead to confusion and distress.

Consider also the other end of a spectrum where a person grows up in a safe predictable resource-abundant environment. Their behaviors and cognitions would have developed to suit that particular environment. If this person were placed in a situation where their future was no longer predictable, for example, losing paid employment so that their financial future is no longer predictable, or being exposed to uncertainty about an intimate relationship (e.g., perhaps they were attracted to a fast strategist; see Marcinkowska et al. 2016), this would also lead to confusion and distress as their cognitive-emotional blueprint for the future and how to operate in the environment is no longer relevant. There may also be a tendency for slow strategists to set extremely high expectations about themselves and others that may be realistic in one environment given their early experiences; however, completely unrealistic in a different environment. Failure to meet these high expectations can lead to people to experience anxiety, frustration, anger, and low self-worth (symptoms of depression).

While there is no empirical evidence at present to support the notion of rigid expectations leading to psychopathology, there is case study support. The first author is a practicing clinical psychologist who has treated numerous clients who would fall all along the fast-slow continuum and who have all being diagnosed with various “psychopathologies.” Over the years he has observed a tendency for clients to express expectations that do not meet their current environmental context, with these

rigid expectations the apparent underlying cause of their psychological distress, which ultimately manifests itself in various psychological disorders. Conceptualizing mental health problems within a life history framework and removing judgments and assumptions about whether particular behaviors are pathological can help clinicians understand the role and historical function of the behaviors, cognitions, and traits that characterize clients’ presenting problems.

Conclusions

Life history theory provides a robust testable framework that helps researchers to organize their thoughts and their findings in a coherent manner consistent with evolutionary theory. The theory explains across species, within species, group, and individual differences. Application of life history theory to the human experience allows researchers to conceptualize and understand the roles and functions of variations in human behaviors from pubertal timing through to psychopathology. While empirical research investigating the psychological phenomena from a life history perspective is still in its relative infancy in comparison to other theories, what has been done to-date has significantly changed the way people think about human development and gene $\times$ environment interactions. The next step in the process is the application of life history theory to a number of already established subfields in psychology.

²Department of Psychology, University of Arizona, Tucson, AZ, USA

Synonyms

Sexual assault; Sexual coercion

Definition

Rape is usually defined as a sexual assault involving some form of oral, anal, or vaginal penetration without the consent of the victim; such penetration may be accomplished either through the use of physical force or threat of bodily harm or when the victim was unable to give consent due to lack of consciousness or intoxication (Koss and Figueredo 2004). The occurrence of a rape may be assessed using self-report questionnaires such as the Sexual Experiences Survey (Koss et al. 1991; Koss and Oros 1982) or the Sexual Acts and Perceptions Inventory (Sisco and Figueredo

2008), typically without explicitly using the word “rape” but instead by providing descriptions of the acts.

Inextricably associated with the formal definition of rape is the question of whether it should be considered to be a “violent” or a “sexual” offense. As with intimate partner violence (IPV), which is highly correlated with marital rape (Figueredo and McCloskey 1993; Figueredo et al. 2001, 2009; Figueredo et al. 2017), feminist theorists consider rape to be a crime of violence against women, whereas evolutionary theorists generally emphasize the sexual dimension of the offense (Figueredo 2001). As most sexual assaults are perpetrated by acquaintances rather than strangers (see Koss et al. 2016), it has even been argued that the difference between rape and IPV is primarily a socially constructed one (Figueredo 2001), perhaps based on the historical definition of “spousal abuse” having required the intimate partners to have been legally married. In rape as in IPV, the sex and the violence cannot be disentwined simply by formulating mutually exclusive definitions. Nevertheless, all reasonable positions considered and in fairness to all parties in this polemic, one might conclude that most sexual assaults are ultimately *motivated* by sex in the perpetrators yet generally *experienced* as violence by the victims (see Thornhill 1996; Thornhill and Palmer 2000).

Introduction

The received view within the standard social science model (SSSM) is primarily derived from the feminist theory of patriarchy (Brownmiller 1975; Figueredo and McCloskey 1993; Figueredo et al. 2001, 2009), which purports to explain both physical and sexual violence toward women as the products of entrenched sociocultural arrangements, such as structural and status inequalities between the sexes disfavoring women that are ultimately founded on the ideology of patriarchy.

The alternative view within evolutionary psychology (EP) is primarily derived from the work of Thornhill and Palmer (2000), who present two alternative evolutionary hypotheses. The first, championed mostly by Thornhill, is that male

sexual coercion of females has possessed adaptive value over evolutionary time and has thus been directly selected for as a behavioral adaptation, analogous to those observed in a variety of other species of insects, birds, and mammals. The second, championed mostly by Palmer, is that male sexual coercion is a by-product of other evolved adaptations, such as greater male size, strength, and aggressiveness as compared with female humans, coupled with elevated male sexual motivation (see Figueredo 1992).

Elaborations of these theories include competitively disadvantaged male (CDM) theory (Figueredo and McCloskey 1993) and the mate deprivation (MD) hypothesis (Lalumière et al. 1996). Both CDM and MD theories predict that perpetrators of sexual coercion will disproportionately be males who are at a strategic disadvantage in the mating competition at obtaining or retaining female partners, as a result of deficiencies in sexually desirable traits such as social status, financial resources, or physical attractiveness. Lalumière et al. (1996) sought to test this hypothesis by demonstrating that sexual offenders were somehow able to obtain comparable numbers of sexual partners to non-offenders, which they were able to document, but failed to provide evidence that these sexual contacts were all consensual; this is an important omission as it has been found that the cognitive distortions prevalent among sexual offenders include heuristics for inferring partner consent that deviate substantially from accepted social norms in contemporary Western cultures (Sisco and Figueredo 2008).

Another important question, even within EP, is whether sexual violence is explained most adequately by theories that are specific to sexual coercion as an evolved adaptation (Thornhill and Palmer 2000) or by theories that are general to social deviance, including other violent but non-sexual offenses (Figueredo et al. 2000a). Recent empirical work has called into question the discriminant validity of the concept of IPV in relation to generalized interpersonal aggression and, thus, by implication, that of sexual coercion (Figueredo et al. 2017); once again, these separate categories might primarily be differing sociohistorical constructions based upon similar or perhaps even

identical phenomena, as seen through various cultural and ideological lenses, as there do not appear to be very defensible demarcations among them that can be derived either from the empirical evidence grounding them or from the nomological network of theoretical constructs surrounding them.

The Role of Life History Theory

Life history (LH) theory is a theoretical framework used in evolutionary biology to describe how and why individuals allocate varying amounts of bioenergetic materials into two competing areas: somatic or reproductive effort (Figueredo and Jacobs 2010). Somatic effort describes the amount of effort an organism invests in its own growth and preservation; the body requires a certain level of caloric energy to complete basic functions like digestion, cell turnover, and homeostatic maintenance (Ellis et al. 2009). Reproductive effort refers to an organism's effort to propagate their genes into the next generation. Under the reproductive effort heading, there are two main goals: mating effort and parental effort (Ellis et al. 2009; Figueredo et al. 2015b). Mating effort consists of investing time and energy into acquiring sexual partners, while parental effort refers to investing energy into the development and survival of an organism's offspring and kin.

LH theory describes how intrinsic and extrinsic threats in the evolutionary and developmental environment update the biology of individuals, selecting for the most advantageous survival strategy. LH theory predicts that when an individual's environment is stable and predictable, one will invest more into somatic effort, rather than reproductive effort. For instance, as the environment is predictable and a future can be reliable upon with a reasonable amount of certainty, an organism can expect time to invest in growing long bones or developing a large brain. Conversely, if the developmental or evolutionary environment was dangerous and unpredictable, with varying degrees of harshness at any given time, an organism would invest more in reproductive effort. When environmental threat levels are high, it is most productive

to develop and reproduce quickly, ensuring their genes will have a chance to be passed on to the next generation.

The latent LH construct consists of a constellation of different manifest indicators. Collectively, these indicators construct an individual's LH strategy along a continuum that ranges from fast to slow (*low to high K*; Figueredo and Jacobs 2010; Ellis et al. 2009). In its original conception, LH theory made predictions about observable, biological outcomes between species such as parental investment, inception of puberty, age of first sexual activity, or age of first birth (MacArthur and Wilson 1967; Pianka 1970). Faster species were predicted to evolve traits that would facilitate reproduction: (1) earlier pubertal timing, (2) more mating partners, (3) earlier first parturition, (4) more offspring, or (5) lower parental investment compared to their slow counterparts. As previously mentioned, slower species were predicted to first invest in their own growth and preservation and then in their offspring; they were predicted to have (1) later first parturition, (2) fewer offspring, (3) high parental investment, and (4) extended lifespan. Humans are slower life history strategists as we have a long juvenile dependency period and life spans that can last up to 100 years (Kaplan et al. 2000). There is visible variation within our species, however, which can be measured in traits such as female initial age of menarche, number of children, or interbirth interval.

In addition to measuring the biological outcomes of humans, LH makes predictions about psychological attitudes (Figueredo et al. 2015a). For example, understanding LH theory can shed light on why some individuals are more inclined to engage in long-term rather than short-term relationships, have few or multiple sexual partners, or maintain negative or positive attitudes toward casual sex (Patch and Figueredo 2017). Faster individuals, due to their more uncertain, unpredictable developmental environment, display a constellation of psychosocial traits selected to increase their proximate (and as such, ultimate) goal of mating effort; they are promiscuous, impulsive, less rule governed, and more likely to engage in risky behavior (Figueredo et al. 2015a;

Olderbak and Figueredo 2010). Additionally, faster LH strategists are more socially deviant (Figueredo and Jacobs 2010). The confluence of an adaptive strategy focused on mating effort and socially deviant behavior might lead to sexually deviant attitudes and behaviors.

Disparate LH strategies have disparate goals related to mating and relationships. Faster LH strategists tend to take an antagonistic social approach toward mating, regardless of the sex of the individual with whom they're interacting. For instance, a faster LH male might display controlling behaviors such as aggressive mate guarding or interpersonal violence more broadly, while fast female LH strategists might engage in competitive, problematic behavioral displays and interfere with a male's other potential mates. These mating differences can be seen cross-culturally (Weiss et al. 2004; Salmon et al. 2009).

Faster LH strategists expend more energy on mating effort and, as such, more energy acquiring mating partners, even those from whom they do not have consent. For faster LH strategists who have disagreeable personalities (Paulhus and Williams 2002), discount the future (Jonason et al. 2016), and are more promiscuous (Patch et al. 2017), rape may be an adaptive tactic. One manifest indicator of LH strategy, early sexual debut, has been shown to predict the level of delinquency later in life in a specific individual and also in their siblings; that is to say, if one sibling has experienced an early age of first sex, early age and level of delinquent behavior can be predicted in not just their own behavior but even that of their siblings (Figueredo et al. 2000). As early sexual debut predisposes adolescents to delinquency, sexual coercion might merely be the interaction between two components of a faster LH strategy: a proclivity for violence and an emphasis on mating effort (Figueredo 1992).

Recently, researchers have been examining a third component of faster LH strategists' personalities that might additionally increase their levels of sexual coercion: dark triad (DT) personalities (psychopathy, narcissism, Machiavellianism; Paulhus and Williams 2002; Jonason et al. 2009; Patch et al. 2017). DT personalities (i.e., callous affect; grandiose, manipulative, and impulsive

nature) have, as of late, been examined through an adaptive lens, particularly because these socially problematical personality traits persist in the population in spite of societal efforts to eradicate them. Among the reasons for the persistence of such traits is the possibility that the latent common factor underlying the three DT personalities is an expression of faster LH referred to as an "exploitative short-term mating style" (Jonason et al. 2009), which is a sexual strategy purportedly based upon the belief by males that they have "divergent interests" from those of females within sexual relationships (Figueredo et al. 2012; Malamuth 1998), generating a greater likelihood of conflict with their partners. Although faster LH does not necessarily imply the possession of DT traits, such an exploitative sexual strategy is more consistent with the uncommitted and promiscuous sexual lifestyle of faster LH individuals. Exploitative sexuality, and especially sexual coercion, would be more clearly inconsistent with slower LH.

For example, faster LH does indeed significantly predict psychopathic personality (Patch and Figueredo 2017). Furthermore, faster LH strategists and psychopathic individuals have similar characteristics and goals, such as a preference for casual sex, higher number of mating partners, and report higher than average levels of relationship conflict and dissolution (Jonason et al. 2009; Olderbak and Figueredo 2010). Both groups' goal is to exploit short-term mating opportunities even if that harms their partners. Both groups, additionally, demonstrate higher than average levels of aggression and criminality (Jonason et al. 2016). As dark triad personalities' common core is a profound lack of empathy, not obtaining consent from a potential mating partner would not constitute a moral dilemma (see also Sisco and Figueredo 2008).

As with the two major EP alternative theories of rape, we may question whether the exploitative sexual strategies represented by DT traits are maintained in the population by selection as a direct consequence of their function in facilitating sexual coercion. Alternatively, it might be the case that the faster LH strategies that might ultimately lead to exploitative sexual strategies, albeit

indirectly, are being maintained in the populations by selection as a consequence of their function in facilitating more generalized antagonistic social schemata and behavioral strategies as psychological adaptations to harsh and unpredictable environments of evolution and development.

Conclusion

We have surveyed the varying definitions of rape in relation to the juxtaposition of its sexual and violent elements. We have then examined the major evolutionary and non-evolutionary theories that have been proposed for the etiology of sexual coercion, including the specific adaptation and by-product hypotheses, following up on some of the novel predictions generated by these two perspectives and evaluating them in light of the empirical evidence. We then considered whether sexually coercive behavior is best explained by domain-specific or domain-general evolutionary theories, calling into question the conventional wisdom that has created arbitrary distinctions between rape, intimate partner violence, and interpersonal aggression in general, whether specifically sexual or not in any given instance.

All of these considerations have been made within the context of life history theory, which provides an overarching framework from which to view sexually coercive behaviors as a subset of sexual behaviors in general, as governed by regulatory mechanisms that control the allocation of bioenergetic and material resources among different components of fitness, including those specifically allocated to mating effort. In so doing, we have considered the specific role of DT personalities as specific manifestations of faster LH strategies that might be evolved and developed with the function of producing exploitative sexual strategies that facilitate the production of sexually coercive cognitions behaviors.

Biography of Charles Darwin

Definition

The life of Charles Darwin is examined including his education, main writings, and influences.

Introduction

Charles Darwin was an English naturalist who made significant contributions to the fields of geology and biology. His most famous contribution was a theory to explain the mechanism of evolutionary change which he called natural selection. While there were debates during his lifetime about whether or not natural selection is the main mechanism of adaptive change, today his theory is well accepted by mainstream biologists.

Early Years and Education

Charles Robert Darwin was born on 12 February 1809 in Mount House on the outskirts of the English town of Shrewsbury. His parents, physician Robert Darwin and pottery heiress Susannah Wedgwood, were a wealthy property-owning couple who had five other children.

Charles, who was known to his family as “Bobby,” failed to distinguish himself at Shrewsbury School and maintained this trend when, at the age of 16, he went up to Edinburgh University to study medicine. There he proved to be a rather lazy (and queasy) student who spent more time hunting and drinking than studying for his medical degree. Despite this lack of effort, Charles was fortunate in joining a natural history group known as the Plinian Society. There he met and was greatly influenced by physician Robert Grant, who helped to stimulate his interest in marine invertebrates (Desmond and Moore 1991). He also attended a number of talks on natural history where the concept of evolution is known to have been discussed. After 2 years, Charles left Edinburgh and changed direction when he entered Cambridge University to study for the clergy. At this stage in his life, Darwin did not appear to have strong views on religion either

way, but rather found the idea of becoming a country parson an attractive one (Browne 1995). At this time, students studying for a BA degree at Cambridge were allowed a great deal of latitude in which areas they chose to study. Darwin was extremely fortunate in choosing both botany and geology. During the 1820s, Cambridge had two world-renowned naturalists in Professors John Stevens Henslow and Adam Sedgwick, who ran botany and geology classes, respectively. In fact Darwin was fortunate in two respects in taking their classes. First, both of these experts were cutting-edge researchers and captivating teachers, and second, both later played a part in setting up Darwin’s famous voyage on board the *Beagle*. In the case of Sedgwick, a geology trip with Darwin to Mid Wales stimulated the younger man’s enthusiasm and working knowledge of this newly emerging science. This, in turn, stirred his interest in traveling widely in order to examine the rock formations around the world. In the case of Henslow, the link to the *Beagle* was somewhat more direct.

Having graduated in January 1831 (coming a respectable tenth out of a class of 178), Darwin was all set to follow the path of a country parson, when a letter arrived at Mount House which would set him off on a very different path. The letter offered him a position on a 4-year circumnavigation survey voyage of *HMS Beagle*. Interestingly, Henslow had originally been offered the role, but rather than spend this lengthy period away from his family, he suggested Darwin as a young alternative (Workman 2014).

The Voyage of the Beagle

On 27 December 1831, *HMS Beagle* set sail from Plymouth harbor under the captaincy of 26-year-old Robert FitzRoy. FitzRoy was given command of the ship following the suicide of its previous commander Parker King. It’s often reported that Darwin was appointed as ship’s naturalist, but in fact that position was taken by surgeon-naturalist Robert McCormick. Darwin’s appointment at the start of the voyage was as captain’s companion. This rather vague position probably arose as a

consequence of the fact that suicide had become common among commanding officers on such lengthy voyages (Browne 1995). Not only did Darwin have no professional role on board, but the 22-year-old was also expected to pay his way to the tune of more than £1500 (£73,000 in today's money which his father, after some persuasion, agreed to finance).

The young Darwin took some time to find his “sea-legs” and spent much of the early part of the voyage sick in his cabin. As he recovered, he was fortunate that his cabin was also the ship's library containing some 400 books (including a number of up-to-date works on natural history and geology). Of particular importance was a copy of the first volume of Charles Lyell's recently published *Principles of Geology*. Having this groundbreaking work proved to be yet another fortuitous event for Darwin as it introduced him to the concept of *uniformitarianism*. This is the theory that the planet has been, and continues to be, shaped by gradual, but observable, geographical changes. The action of a river running through an area, for example, can lead to the formation of a valley. Moreover, more rapid changes can also occur when, for example, due to an earthquake or the eruption of a volcano, the landscape can alter quite radically. Interestingly, in the third volume of *Principles of Geology*, which Darwin picked up later on in the voyage, Lyell even discusses the gradual birth and extinction of species.

Darwin's Relationship with FitzRoy

During the voyage that was to survey, among others, much of the coast of South America, the Galápagos Islands, Tahiti, Australia, and Mauritius, Darwin's main confidant was, of course, FitzRoy. Their relationship started off very convivially with the two men taking it in turns to read Jane Austin aloud to each other. As the voyage progressed, however, cracks began to appear, and their relationship developed into a love/hate one. Although the two men had great respect for each other, they also engaged intermittently in a number of running debates. While both were from wealthy backgrounds and

both had a prodigious intellect, as the voyage progressed, they fell out on topics such as religion and the slave trade. FitzRoy was a man of religious piety and considered that God had put us on earth to direct those races which he considered inferior to white Europeans. This made the slave trade acceptable to him. Darwin, for his part, perceived continuity between people of different races and saw slavery as an abomination. Despite his unsavory views on race and slavery, or rather because of them, FitzRoy may well have aided Darwin in the formation of his ideas about evolution. When he began to turn his attention to the mutability of species, FitzRoy's counter arguments ensured that Darwin had to be very cautious with how he expressed such radical thoughts on his return home (Workman 2014). This no doubt stood him in good stead when he finally published his theory of evolution some 20 years later (FitzRoy had also read Lyell's book).

The Origin of the Origin of Species

When Darwin made landfall in South America, he determined to spend as much time as possible on land observing the flora and fauna and examining in some detail the geology of the coast. One thing that struck him almost immediately was that fossils of the upper rock layers were more similar to extant species than those of the lower strata. To Darwin, this suggested species had gradually modified over a geological time scale progressively becoming more similar to modern-day ones. Later, when he arrived at the Galápagos Islands on the west side of South America, he began to shift his attention from geology to biology. In fact by the time they reached South America, Darwin had pretty much usurped the McCormick in his role as ship's naturalist (the latter man left the *Beagle* in Rio due to Darwin's developing obsession with geology). On the Galápagos, Darwin made further observations which strengthened his view that species were not immutable. In particular, he noted how the finches and giant tortoises appeared to have specific features which helped them exploit potential food reserves on each island. The shape and size

of the beaks of specific species of finch, for example, allowed them to overcome the challenges of food extraction that each island (and areas within each island) presented. Where seeds required opening, for example, the finches had short robust beaks, whereas when grubs required extraction, then the finches had developed slim probing beaks. In considering the origin of species, these sorts of observation led Darwin to speculate that such species had arisen from a common ancestor and then changed in ways that helped them to exploit food resources (and other aspects of the environment). He did not at this point, however, have the mechanism for such evolutionary change. That was to come much later on.

Back in England

When Darwin arrived home in England (sailing into Falmouth port on 2 October 1836), he brought back with him two major observations. First, organisms change and become progressively more like current living ones as we move up the geological strata, and second, organisms are well designed to deal with the challenges of their local environment. What he needed now was a mechanism or principle to explain these observations. At this stage in his life, he was already gaining a reputation as a geologist. This might sound surprising, given he was away for what became nearly 5 years. In fact he was surprised at how established his reputation had become. There was, however, a logical reason for this rise in standing; every time he put into port, he arranged for letters outlining his thoughts, observations, and samples he had collected to be sent back to Henslow and Sedgwick (Burkhardt and Smith 1986). Such thoughts included an explanation for the formation of marine atolls and the concept of the world being much older than was currently accepted. Note in both of these matters, Darwin was later proved correct. For their part, recognizing the quality of Darwin's field work, Henslow and Sedgwick shared his ideas at prominent meetings and via their published work. Darwin was duly elected a Fellow of the Geographical Society. His reputation as a

biologist was to come later following years of work on barnacle anatomy and later, of course, through his development of the theory of evolution by natural selection (Desmond and Moore 1991).

Marriage to Emma and Family Life

During the late 1830s, Darwin concentrated on two things: first, writing letters, books (including the best-selling *Voyage of the Beagle*), and articles and second, getting married. In both of these endeavors, he demonstrated his usual scientific methodology. His writings, while somewhat long-winded by today's standards, were clear and long-sighted. This was also the case when he decided to begin courtship. The target of his affections was his cousin Emma Wedgwood. It's clear that he had affection for Emma, but prior to determining whether this might be reciprocated, he devised a list of pros and cons with regard to marriage. On the con side, he listed "less money for books," whereas on the pros side, he wrote a "constant companion, (and friend in old age) who will feel interested in one, – the object to be beloved and played with. Better than a dog anyhow." Fortunately for Darwin, he went with the pros side of the equation, and Emma did reciprocate his feelings. The couple were married in a small chapel in Maer on 29 January 1839. Following 3 years living in Upper Gower Street in London, in 1842, the couple bought a country house in Downe in Kent. This large manor house, somewhat confusingly, was known as Down House (note the slightly different spelling), and there, they remained for the rest of Charles' life.

Despite Darwin's apparently utilitarian approach to marriage, it is clear that the couple did love each other and in fact, although his writing style would be considered rather formal by today's standards, he was a man well able to demonstrate affection to his loved ones. Emma, for her part, proved to be a caring and attentive nurse as, following his return, Charles succumbed to regular bouts of ill-health. And despite her strong religious convictions and misgivings

about the concept of evolution, Emma also played a large role in correcting his grammar and spelling. The couple had ten children, seven of which survived childhood. Charles proved to be a caring father, and, in common with Emma, he suffered greatly when three of his children died. He clearly enjoyed the company of children, and when his boys were old enough, he liked nothing better than to play a game of billiards with them of an evening.

Back to Evolution

By the time of his marriage to Emma, Charles had begun to keep notebooks noting down his thoughts on the topic of evolution (although at this time, he largely used the term of “transmutation”). Drawing on his experiences on the *Beagle*, he made a number of false starts, but by the end of 1839, he had managed to put all of the pieces of the puzzle together to complete a picture of how evolution occurred. He called this natural selection. To be clear, Darwin was not the first person to come up with the concept of evolution. The idea of organic evolution had been around since the time of Aristotle. (Interestingly Charles’ grandfather, Erasmus Darwin, had devised his own somewhat fanciful theory of evolution back in 1777 suggesting that efforts animals made during their lives, could alter their characteristics in positive ways and that such improvements are then passed on to their offspring). What the younger Darwin did was to add two elements to the concept of evolution. First, he proposed the mechanism to explain how evolutionary change occurred, and second, he marshaled the evidence to support this theory. The crux of the matter can be seen on page 7 of his first “transmutation” notebook:

According to this view, animals on separate islands ought to become different if kept long enough apart, with slightly different circumstances (Burkhardt and Smith 1986).

According to Darwin, natural selection involves three elements. First, there is heritability, which means that each offspring has similar traits to its parents when compared with other members

of the population. Second, there is variation, that is, members of a population vary in heritable ways. And third, members of a population have differential reproductive success. Hence, due to heritable variability in a population, some individuals have a competitive advantage in relation to survival and reproduction when compared with others in a specific environment. Natural selection later became known as “survival of the fittest,” a term first used by another English evolutionist Herbert Spencer (Browne 1995).

We might ask just how did Darwin derive the concept of natural selection? This was in effect the logical outcome of combining his earlier observations (fossils become more like current living species and organisms are particularly suited to their environment) together with two major works of science. The first of these was Lyell’s *Principles of Geology* and the second was Thomas Malthus’ *An essay on the Principle of Population* (published in 1798). Malthus had argued that, because populations grow faster than food availability, starvation led to the winnowing out of less competitive individuals. Combining this with Lyell’s notion of gradual but constant environmental change, Darwin saw that, as the environment changed, different adaptations were selected by “nature,” hence natural selection.

Friends and Allies

As Darwin’s standing rose, he found he was often visited by eminent naturalists of the day. Many become close friends and supporters. Of particular prominence were three men: the aforementioned Charles Lyell, Joseph Hooker, and Thomas Huxley. It is worth considering each of these briefly as they all proved to be important to him when he launched his radical ideas about evolution onto the world.

Although Charles Lyell had many achievements in the field of geology (for which he was later knighted and then made a baronet), his reputation was secured when he published *Principles of Geology*. By the time Darwin returned to England, Lyell, who was in his 30s, had become professor of geology at King’s College. He

recognized the originality of Darwin's writings, and very rapidly, the two men become close friends. This friendship was to prove beneficial to both men as each drew on the others writings (Darwin would draw on the *Principles of Geology* and Lyell modified later editions of this three-volume work to incorporate Darwin's ideas on evolution). Joseph Hooker was the first person to bring together the fields of botany and geology to create the field of botanical geology. Like Lyell, he was an avid reader of Darwin's work and also become a close friend following an invitation to classify the plants he had gathered in South America. He later went on to become director of the Royal Botanical Gardens in Kew. Despite the close friendship and support of Lyell and Hooker, arguably Darwin's most renowned supporter was Thomas Huxley. As he was only 11 years old when the *Beagle* returned, it was sometime later that he also became a confidant of Darwin. It was during the 1850s that this largely self-taught natural historian took up Darwin's cause and, in particular, defended him when the *Origin of Species* was published. Huxley's strident defense of Darwin would go on to earn him the nickname of "Darwin's bulldog." He later went on to become professor of natural history at the Royal School of Mines in 1854 and was the first person to suggest birds had evolved from dinosaurs.

During the early 1840s, Darwin shared his concept of natural selection with all three of his confidants (and a few others). This included a 35-page essay in 1842 which 2 years later he fleshed out into a more detailed 50,000-word essay (Darwin 1842; 1909). Although all three encouraged him to publish, at this point he held back, probably due to the fact that he was still gaining supportive evidence via his regular correspondence with experts from around the world. During the 1850s, he was working on a mammoth outline of his theory which was planned to be two volumes long. This plan, however, had to be put aside when out of the blue in February 1858, he received a letter outlining the same process in 20 pages. The letter was from another British naturalist, Alfred Russel Wallace, who was conducting field research in the Malay Archipelago. To Darwin's dismay, the letter

outlined the very same theory of evolutionary change that he had spent so many years developing. While Wallace did not have the supporting evidence that Darwin had uncovered, he had also hit on natural selection through deduction.

Publication and Reception of Origin

Darwin was, as can be imagined, greatly disturbed to find another naturalist had stumbled on natural selection, and his initial response was to allow the younger man to publish ahead of him. Fortunately for Darwin, his supporters talked him out of this course of action, and the theory of natural selection was presented to the world when Lyell and Hooker introduced both men's findings at a meeting of the London-based Linnean society on 1 July 1858.

Following this near catastrophic scoop, Darwin quickly got on with editing his Magnum Opus down to a much shorter (but still 540 pages) account of his theory of evolution. Hence the *Origin of Species* was published on 22 November 1859. To give it its full original title *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* is fortunately, by tradition, generally referred to as *Origin*.

Origin become an immediate best seller with the original print run selling out in 1 day and this leading to a series of follow-up print runs. By and large, the scientific community was positive with most prominent figures immediately being converted to what rapidly become known as "Darwinism" (a term coined by Wallace). In providing an explanation for evolution, Darwin also created a grand unifying theory (GUT) for biology. The importance of this development should not be underestimated as even today biology remains the only science to have a generally agreed on GUT (Workman 2014).

Despite this positive reception, Darwin was not without detractors and critics. These came from both the church and the scientific community (and in some cases continue to do so). One high-powered critic from the scientific community was Sir Richard Owen who at the time was a professor

at the Royal College of surgeons. Owen suggested that many young naturalists had been “seduced” by Darwin’s concept of natural selection. Despite being a man of science, it is clear that Owen’s criticism was fueled by his religious belief.

One prominent figure from the church who questioned natural selection was the infamous Bishop Samuel Wilberforce of Oxford. At a notorious meeting of the British Association of Science in the University Museum in Oxford, a discussion of Darwin’s ideas took place in June 1860. Due to ill-health (and possibly due to the fact that Darwin did not enjoy public speaking), he did not attend, and Wilberforce (briefed by Owen) took the opportunity to ridicule the whole concept of evolution. Fortunately for Darwin, this was an occasion when his bulldog Huxley did attend. Wilberforce asked Huxley whether he had descended from an ape on his grandmother’s side or his grandfather’s side? Huxley’s response was to declare that he would rather be the descendent of an ape than a man of learning who ridiculed scientific progress (Huxley 1900).

Life After *Origin*

Although Darwin was a well-known English naturalist and writer prior to the appearance of *Origin*, following its publication, it’s fair to say, he became a world famous figure. One reason for this was that, in addition to its impact on the scientific community, the book made a large impact in the international popular press. As well as a number of positive reviews, there were also some severe criticisms, and on a number of occasions, he was lampooned in popular publications such as the widely read British satirical magazine *Punch* (in which Darwin appeared as a half ape-half human chimera). His lack of appearance to defend himself at prominent public events due to ill-health became a common theme in the Darwin story. It is fair to say that he was a man who disliked, and hence avoided, confrontation. But, as we have seen, he was fortunate in having an illustrious group of acolytes such as Huxley, Hooker, and Lyell (among others). As his reputation grew, however, he became less afraid of

confronting public opinion in his writings. Although he did not write again about evolution for some 12 years after the publication of *Origin*, when he did so it was with two books which did not shy away from issues many of his Victorian audience would find uncomfortable.

Sex and Emotions: Darwin’s Follow-Up Books on Evolution

Despite his growing fame, during the 1860s, Darwin spent most of his time at Down House where he enjoyed a quiet family life (as well as he was able given his intermittent periods of ill-health). During this period of this life, he continued to write about natural history including well-received, but uncontroversial, works on plants and on domesticated animals. In 1871, however, he turned his focus once more to evolution. In his new work *The Descent of Man and Selection in Relation to Sex* published on 24 February 1871, Darwin exhibited a degree of courage in his writing which had arguably been lacking in *Origin*. Whereas in *Origin*, he had devoted a single sentence to human evolution:

Light will be thrown on man and his origin.

In *Descent*, he dispensed with this diffidence, spelling out the fact that we share with the great apes a simian ancestry. In the final chapter, he confidently stated:

We thus learn that man is descended from a hairy quadruped, furnished with a tail and pointed ears, probably arboreal in its habits, and an inhabitant of the Old World.

The *Descent of Man* was a book in two parts. In the first part, Darwin demonstrated how much we have in common with other species, both in terms of physical features and in relation to behavior. This he took as evidence for evolutionary continuity between us and other species. In the second half, he fleshed out an idea he had briefly introduced in *Origin*, that is, of a second evolutionary force which he called sexual selection. Whereas natural selection is based on the ability to survive and reproduce, sexual selection is concerned with impressing and gaining access to

the opposite sex. This means that, rather than the environment, in effect, the opposite sex does the selecting. Sexual selection helped to explain why males of many species, such as peacocks and mandrills, have more gaudy features than females (because it impresses the females). It also explains why males of many species have a lower threshold for aggressive behavior (to compete with other males). Interestingly, this concept of sexual selection has become very important to the development of modern-day Darwinian approaches to behavior (Buss 2019; Workman and Reader 2020).

The *Descent of Man* is not only a confident book; it is also one in which Darwin speculated about the evolution of a number of human features. In particular, he suggested that human language has parallels with bird song and that it evolved, in part, to impress potential mates. Such ideas were prophetic, as today many evolutionists accept both of these arguments (Locke and Bogin 2006; Slater 2011; Zuk and Simmons 2018).

Why, we might ask, had Darwin's writing style become more confident at this point in his life. It is likely that there are two reasons for this. First, as we have seen, when he published *Origin*, he was becoming a well-known geologist and naturalist. By 1871, his reputation had grown to the point where he was almost certainly the most famous scientist on earth. Second, during the 1860s, a number of fossils had been discovered to demonstrate intermediate forms that were predicted by his theory of evolution. In particular, the first bird/reptile intermediate fossil of *Archaeopteryx* had been uncovered just 2 years after the publication of *Origin*.

As with *Origin*, the *Descent of Man* was generally received positively by the scientific fraternity. This was, once again, by no means unanimous. One area of controversy was the idea that females exerted choice in whom they mated with and the idea that this choosiness, in turn, drove some facets of male features (Cronin 1991). This notion remained controversial for almost a century after the publication of the *Descent of Man*, but following recent research, the evidence is currently overwhelmingly in favor of Darwin's view on this (Buss 2019).

In November 1872, Darwin followed up *Descent* with his final book on evolution *The Expression of the Emotions in Man and Animals*. In this new book, he continued his exploration of continuity between ourselves and other species. In this case, he examined similarities in emotional expression between a range of mammalian species and humans. Based on the observations he made on his travels and through his communications with other experts around the world, he also suggested that people from different cultures used the same set of emotional expressions under the same circumstance. For example, when expressing disgust, anger, and fear, people from very different parts of the world make use of the same sets of muscles controlling the eyes, lips, and nose in exactly the same manner. This suggested to Darwin that the expression of our emotional states arose by natural (and sexual) selection for adaptive communicative purposes. Once again, as with the *Descent of Man*, *The Expression of the Emotions* suggested testable hypotheses (do we all use emotional expressions for the same purposes) which were largely ignored for almost a century. And once again, relatively recent research suggests Darwin was largely right here (Ekman 1992).

The Expression of the Emotions received mixed reviews, and sadly, the people for whom it might arguably have had the greatest impact, psychologists, largely ignored it until recent years (Workman 2014).

Darwin's Theory Misused

Although Darwin's greatest impact was on the development of biology from 1859 on, his influence grew (often unintentionally) well beyond this natural science. One area where his concept of natural selection was arguably misapplied was the field that later became known as Social Darwinism (the term was not used at the time). As the American "Barons" of industry became enamored with the concept of survival of the fittest, they began to see Darwinism as a scientific rationale for ruthless competitive business practices. This notion was based in part on the ideas of

American sociologist William Graham Sumner and British evolutionist Herbert Spencer (Caudill 1997; Workman 2015). Both considered that our natural course was to be competitive and that this was our destiny leading ultimately to some races outcompeting others to the benefit of our species. Ironically, Social Darwinism was non-Darwinian as according to his theory of natural selection there is no predetermined evolutionary path for any species, but rather it is simply a description of responses to recurrent environmental pressures. Also Darwin was well aware that natural selection can lead to the emergence of cooperative behavior. Darwin himself was disturbed by such uses of his theory and distanced himself from such misuses. Sadly, the development of Social Darwinism continues to cause some confusion today (Winegard et al. 2014).

Darwin's Latter Years

Following his latter two books on evolution, Darwin continued to write and study aspects of the natural world, including a work on the beneficial action of earthworms on the soil. He spent much of his last decade at home with Emma, but was regularly visited by his associates and famous figures (including George Eliot) who wished to meet the man who had given the world the first working theory of evolution. At the age of 73, following a 3-month decline in health, he succumbed to heart failure and died in Emma's arms on 19 April 1882. Plans were made for a burial in Downe, but following a campaign by his close friends, he was laid to rest a week later close to John Herschel and Isaac Newton in Westminster Abbey.

Conclusion

In the years following Darwin's demise, the concept of natural selection became modified through the integration of the new science of genetics. This led to the development of "neo-Darwinism" which defines natural selection as "differential gene replication." During the last three decades

of the twentieth century and the first two decades of this century, Darwin's ideas have been integrated into a growing number of academic disciplines. These include evolutionary economics, evolutionary anthropology, evolutionary literary studies, evolutionary psychiatry, and evolutionary psychology to name but a few. Of these fields, published output by evolutionary psychologists clearly dwarfs those from other academic disciplines. Given that Darwin wrote a great deal about the relationship between behavior and evolution, it seems likely that he would have approved of this development.

[Direct fitness](#); [Limited reproductive fitness](#); [Restricted reproductive potential](#)

Definition

The limitation of individuals' reproductive potential due to biological and/or environmental conditions that, in case of being optimum (e.g., good immunity against pathogens and/or environment without resources restrictions), the individual would have maximum offspring number.

Introduction

All individuals have distinct capacity of producing gametes and rearing offspring. As well as good nutrition and sex, genetics are biological factors that differentiate individuals' reproductive potential. However, biological elements are not the only ones to influence reproduction. Environmental factors have the same importance (e.g., diseases, resources, mates, competitors).

Sexual Selection

In 1871, Darwin claimed that the existence of some phenotypic characteristics could not be explained by natural selection due to their incapacity to improve individuals' survival. However,

those same characteristics serve to increase individuals' direct fitness as they enable the ability to attract a greater number of sexual partners or sexual partners with a higher mate value. To this, he attributed the name of sexual selection.

While Darwin considered the mating system to guide sexual selection, Bateman (1948) proposed sexual selection to be the factor that modulates mating system.

Bateman's Principle

Based on Darwin's sexual selection theory, Bateman (1948) conducted a study with *Drosophila melanogaster* to verify if there is a sex difference in intensity of mate selection and, in case it is true, a reason why it exists. He concluded that males tend to have an indiscriminate pattern of mating choice whereas females choose males.

Female's fertility is limited by greater investment of the females, relative to males, in gametes production. As males produce much more gametes than females, there is a competition between the sperm to fertilize the eggs (Bateman 1948). Beyond that, mammal females have gestation and breast-feeding as limiting factors of their reproduction. Males, on the other hand, do not have to invest in gestation and offspring nutrition, which allows them to invest more resources and energy in sperm production and mating effort, in order to increase their reproductive success. Therefore, males would have their reproduction limited by access to females (Bateman 1948).

To this idea, Trivers (1972) attributed the name of **parental investment theory**. He proposed that males and females invest differently in reproduction and offspring, which leads them to have differing reproductive success. There is an intrasexual competition between males (which he called the competitive sex) in order to have access to greater numbers of females (considered the limiting reproductive resource) and as women invest more physiologically in the offspring, it restricts the quantity of children they may have.

Strategic Pluralism Theory

Gangestad and Simpson (2000) theorized based on abundant evidence that environment would determine how women would choose their partners, through a trade-off between men's heritable fitness and paternal investment. In environment with high pathogens indexes, for example, women tend to prefer good-looking partners because beauty (e.g., symmetrical body and face) indicates good immunity. If the environment demands biparental care to guarantee children's survival, women tend to prefer men who are willing to invest in the offspring. Men, in turn, adapt their strategy accordingly to the strategy adopted by women and the access to females would be made possible according to quality of males available in the environment.

In this way, it can be noticed that besides the influence that the access to resources exerts on reproductive potential, the social environment also has its influence as the individual's mate value depends on the quality of same sex individuals available in the environment as well.

Limiting Factors of Reproductive Potential

Being too young is a limiting factor for both sexes, men and women, since before puberty they are not able to reproduce. However, younger women, in general, are preferred as mates because of the short period of reproduction when compared to men. While women stop reproducing when they reach menopause, even though there is a decrease of sperm quality (changes in sperm shape and motility), men still are able to reproduce. Thus, age is a factor that limits women's reproduction and decreases men's fitness (Pawlowski 2000).

Because of the effects that age exerts on female reproduction, their mate value decreases with age. Men, on the other hand, have their mate value increased the older they become, since their reproduction is not limited due to age and the probability of having more accumulated resources increases with time (Kenrick and Keefe 1992). Therefore, it can be taken into

account that resources are important limiting factors of human reproductive potential. As women's investment in children is essential for their survival in the first months, it demands a lot of energy from women who need supplies to provide better conditions of offspring development (Trivers 1972).

Hence, a beautiful body is a characteristic that men give high value when looking for a partner (Buss 1989). Low waist-to-hip ratio, for example, is preferred by men for indicating women's fertility and health. Karremans et al. (2010) justified that women's waist-to-hip ratio is associated with the quantity of fat deposited on the waist and on the hip in women's bodies. Fat located in the hip is positively related to the neural development of the embryo, while the type of fat deposited on waist may jeopardize the neural development. Therefore, physical characteristics may be a factor that reduces human reproductive potential.

1. Operational sex ratio may also be a limiting factor, mainly for males. The number of offspring a female has generally does not increase with greater number of mates. However, the statement is true for males. In a male-biased population, it is even easier to notice how the number of females is a limiting factor of males' reproduction, as there are some occasions in which males do not have the opportunity to copulate (Wade and Shuster 2005). Kruger et al. (2010) study corroborated with this idea for humans showing that in men-biased populations, men tend to marry earlier and younger.

Additionally, operational sex ratio is not the only important factor when talking about mating. Even if there is an equal number of mates of both sexes in a monogamous population (which decreases the odds of a man having access to more women), the pairs will be formed by similarity of mate value, and the individuals who have greater mate value, in general, have higher reproductive success for bonding with the best partners available (Buston and Emlen 2003).

Conclusion

There are several factors limiting potential reproduction: resources, operational sex ratio, and genetics are examples of such factors. Throughout the history of evolutionary psychology, authors have given important contributions toward figuring out diverse aspects of human sexual behavior. Together, all of the theories aforementioned are the foundation for understanding human reproductive potential and what may limit it.

Definition

The multidisciplinary study of linguistic evolution has two overarching goals. The first one is to understand the *origins of language in humans*; in order to do this, anthropologists, archaeologists, geneticists, and linguists examine the biological, cognitive, and technological evolution of our species. Additionally, comparative psychologists and biologists also gain knowledge by identifying similarities and differences between the communicative behavior of humans and other animal species. The second goal of evolutionary linguists is to learn about the *origins of linguistic structure in human languages*. Linguists and psychologists aim at explaining the distribution of linguistic elements and properties as the result of social and cultural evolutionary processes.

Introduction

The term language evolution, or linguistic evolution, is used in two distinct, although related, ways. First, it may refer to the biological evolution of traits that underlie language learning, production, processing, and comprehension in our species. These traits include anatomical features of the language-producing organs and of the nervous system, as well as social and cognitive capacities including advanced imitation learning and cooperation.

Second, linguistic evolution is used to denote the cultural process of language change viewed as a case of Darwinian dynamics or as a complex adaptive system. Linguistic structure adapts to selection pressures originating in modern human cognition and in social factors such as learning and communication processes and population structure.

Language Origin

When Did Language Emerge?

This question “When did language emerge?” has no easy answer. Until recently, language was believed to have emerged with our species,

Homo sapiens, around 100,000 years ago. However, evidence such as the recent sequencing of the Neandertal genome suggests that there are no significant distinctions between the language capacity of that species and modern humans. Therefore, language as we know it may well have been used by the common ancestor of these two species about half a million years ago (Dediu and Levinson 2013).

If the manufacture of complex tools is indicative of the presence of some form of language, the date of language origin may be pushed further back to one million years ago (when Acheulean tools appear in the archeological record) or even to two million years ago (the age of Oldowan tools). Language and toolmaking not only share similar hierarchical, sequential, and combinatorial structure and require similar imitation learning, intention reading, and planned action skills but are also processed by overlapping brain areas (Stout and Chaminade 2012).

Theories of Protolanguage

The structure of early communication systems in the hominin lineage is the subject of extended debate. Questions such as “Did protolanguage have words?” or “Was early language gestural or vocal?” still do not have consensually accepted answers. Describing protolanguage is a difficult enterprise, given the absence of direct evidence. And if we consider language evolution as a gradual cumulative process, protolanguage may never have existed as a single defined stage in the evolution of language (Smith 2006).

Modern languages are mostly compositional (e.g., the meaning of a sentence depends on the meaning of its component words and on the ways in which these are combined) but also some non-compositional, holistic expressions (e.g., “hurray!”, “how do you do?”). Early language could have started off as sets of independent words that were later combined in different ways (Bickerton 1995) or as holistic expressions that were then analyzed or broken down into elements which eventually developed into words as we know them (Wray 2002).

Most of our linguistic behavior occurs in the vocal modality, but vocal control in our closest

ape relatives is poor. Language, therefore, may have begun its existence in the manual, or gestural modality, perhaps as pantomime and pointing, and later switched to the vocal modality (Corballis 2002; Tomasello 2008). Or it may have started off, as the musical protolanguage hypothesis suggests, in the vocal modality, in the form of songs or calls – not unlike the vocalizations of vocal learner species – which were then co-opted for communicative purposes (Fitch 2010). Alternatively, gesture and vocalization may have coexisted in language since its inception. Gesture is well suited to convey meanings iconically – iconic signals resemble their referents. But iconicity has limitations for the communication of abstract concepts. Early iconic gestures may have been accompanied by vocalizations, which gradually became symbolically or arbitrarily associated with aspects of the meaning, until they became the dominant communication medium. This third hypothesis avoids questions about the transition from the gestural to the vocal modality and about the origin of singing or other forms of noncommunicative vocalization, while simultaneously acknowledging that co-speech gesture is an integral component of modern language (McNeill 2012; Arbib 2012).

Biological Language Evolution

The study of the biological evolution of language is informed by evidence from a number of complementary sources. The fossil record of bones and the artifacts left by our ancestors gives us a glimpse of the skeletal structures and the culture present at different stages in our evolution. Comparative studies focus, on one hand, on species closely related to humans, such as chimpanzees and other primates, and, on the other, on more distantly related species including songbirds and marine cetaceans that share a key cognitive capacity with us, namely, vocal learning. The first kind of comparisons allows us to establish which language-related traits were present in our ancestral lines and which have evolved specifically in our lineage, while the second helps us understand which anatomical structures and

cognitive skills underlie the different components of language.

We share with our close primate relatives – and, presumably, also with our most recent common ancestors – well-developed social intelligence and communication skills. Some monkey species have alarm calls to warn the group about specific dangers, and others combine calls flexibly to alter the call meaning (e.g., Zuberbühler 2015). The great apes routinely communicate with each other through gesture and simple vocalizations, and chimpanzees are able to create and use stable signals through ontogenetic ritualization, a social process that gives rise to refined communicative signals, and may happen, for example, when a baby chimpanzee lifts its arms on several occasions in order to climb on its mother; the mother learns to respond to the arm-lifting gesture by picking the baby up before the baby has a chance to climb. Over time, the baby only needs to move its arms up slightly for the mother to respond (Tomasello and Call 1997).

However, monkey alarm calls are mostly innate; nonhuman primate signal combinations are extremely limited; and ritualized signals are confined to the pair who created them and do not spread to the population. Human language, a unique communication system, that is, simultaneously structured, conventional, and socially learned, only exists in the context of the unparalleled scale of human social cognition skills such as imitation and cooperation displayed by humans.

Brain Size

The fossil record attests to a rapid evolution of the brain volume from 400–500 cm³ in the Australopithecines about four to five million years ago to 1500 cc in Neandertals 400,000–30,000 years ago, with a recent volume decrease to the modern human average of about 1200 cc. An increase in brain size, however, provides only indirect evidence of the evolution of language. Changes in brain size and structure may have evolved in response to cognitive demands originating in technological advances or in larger social groups. A cultural novelty, cooking, could have supported these anatomical changes. Cooked food is easier

to digest and provides a much more higher nutrient intake than raw food; the extra resources could then supply the expanding brain (Wrangham 2009).

Speech Production

The speech-producing organs also underwent important changes in hominins, including a reshaping of the oral cavity and the loss of the air sacs present in other great apes, that extended the range of sounds that could be produced. The new elongated pharynx, however, makes us more prone to choking, and this fact has been put forward as evidence for the adaptiveness of phonemic variation – the fitness increase derived from improvements to speech must outweigh the fitness cost of an increased choking risk (Lieberman 2007).

Cooperation

Unlike other apes, humans spontaneously cooperate with and expect cooperation from others from a young age. We are able to direct others' attention toward potential points of common interest, to read others' intentions, and thus to entertain joint goals (Tomasello 2008). We also conform to social norms sometimes against rational judgment (e.g., Asch 1951), and strong conformity allows us to have cohesive societies and also facilitates cooperation. There are close interactions between cooperation, joint intentionality, conformity, and linguistic communication which would boost the fitness of individuals who excel at those traits. Being able to read others' intentions and establish joint attention is important for learning the conventional associations between words and their meanings. Language facilitates cooperation by mediating communication about potential opportunities and risks and by planning and sharing joint goals. And linguistic encoding enables the establishment and enforcing of complex social-cultural norms and traditions.

Imitation Learning

One of the main language-related evolutionary innovations in our lineage is advanced imitation. Humans share a particular aspect of imitation learning called vocal learning with a few other

distantly related species. Vocal learning is the capacity to learn and reproduce the vocalizations of conspecifics and is mediated by an enhanced motor control of the articulators, notably the tongue and of muscles involved in breathing, and by the highly developed capacity for imitation. This high-fidelity transmission mechanism has evolved independently in a heterogeneous group of species that includes some songbirds, cetaceans, elephants, and bats. Some vocal learners produce complex sequences which are made up from smaller elements, or motifs, recombined in different ways, persist for many generations, undergo cultural evolution, and diversify into dialects associated with different populations of the same species (Slater et al. 1984).

In humans, however, imitation is not limited to vocalization. We are, from a young age, avid imitators of all kinds of behaviors, much more so than our closest relatives. While chimpanzees engage in emulation (a form of social learning in which the copier reproduces the goals of an action, but not the precise behavioral sequence to achieve it) and occasionally sometimes in imitation (reproducing both the goal and the behaviors), humans are much more prone to doing imitation and also overimitation (copying actions in a sequence that are irrelevant or unnecessary to achieve the desired goal) (Whiten et al. 2009). The high-fidelity copying enabled by imitation and overimitation is a key causal factor in cumulative cultural evolution. The abovementioned effects of vocal learning on the complexity and diversification of birdsong are but a shadow of the effects of imitation learning on all realms of human culture, including technology, art, and language.

Cultural Language Evolution

The newly evolved social and cognitive traits, notably those that increased the fidelity of social transmission, paved the way for a new evolutionary system, human culture. Traits of cultural traditions such as the length of a spear, the design of a vase, or the set of phonemes in a language can

now persist for many generations and be the subject of evolutionary forces such as mutation and selection.

Language Change as an Evolutionary Process

Historical language change can be construed as the Darwinian evolution of population linguistic traits (Croft 2000; Ritt 2004). These traits include words, phonemes, phonetic variants, morphosyntactic constructions, and prosodic patterns. New variants of the traits arise during the course of language use, when speakers innovate or make mistakes in production or comprehension. Some variants are fitter than others – they are more likely to be adopted or used by speakers and consequently to spread and become the conventions of a language. Cultural language evolution is guided partly by chance factors – in evolutionary terms, by random drift – but also, more interestingly, by selection processes formally equivalent to natural selection, but mediated by cultural instead of biological processes.

Linguistic traits adapt to selective pressures related, among others, to the social prestige of the speakers who use them; to ease of production, processing, or comprehension; or to how well they fit in with the rest of the traits in the language. Some traits – for instance, core vocabulary items – are transmitted with such high fidelity over the generations that they can be traced back thousands of years (Pagel 2009). Most, however, change faster, and as innovations accumulate in separate populations, they give rise to linguistic variants, dialects, and eventually mutually unintelligible languages.

Language also adapts culturally to other aspects of the niche in which it evolves, including the structure of the social group and communicative function. Languages that are spoken in large, open societies tend to be morphologically simpler than those spoken in small, close-knit populations. This may be due to the presence in the open populations of adult learners for whom complex morphology is taxing. In smaller, closed groups, where speakers share more common ground and most learners are children – who are good at learning complex morphology – complexity can accumulate (Lupyan and Dale 2010).

The patterns of variation observed in world languages are, therefore, the result of processes of descent and modification from ancestral languages. From present-day variation, phylogenetic analysis can infer language trees or networks analogous to those used to map biological species. Combined linguistic, geographical, and historical data can not only trace the ancestry of language families but also help establish their geographical and temporal origins (Bouckaert et al. 2012).

Emergent Languages

Occasionally, a new language spontaneously emerges in a newly formed group of speakers who do not share a common language. This is the case of pidgin and creole languages, of sign languages in populations with high prevalence of congenital deafness (Meir et al. 2010), and of sign languages in newly opened schools for the deaf which bring together children who never had full access to language before (Senghas and Coppola 2001). In these groups, an initially ad hoc, variable, and unstructured communication system gradually acquires, usually within a few decades, the properties of modern, full-fledged natural languages, including a phonological system and productive morphology and syntax.

Experimental models of cultural language emergence show that when language transmission is disrupted, linguistic structure becomes simple and compressible; when languages are used communicatively, they develop or maintain distinct words for different meanings. A core property of language, compositionality, whereby a limited number of elements and rules can be productively recombined into countless utterances, emerges as an adaptation to the two simultaneous but conflicting pressures for compressibility and expressivity (Kirby et al. 2015).

These singular cases and models clearly demonstrate that for linguistic structure to emerge, both biologically modern humans and social processes such as communicative use and transmission to new learners are required: a population of members of another species does not spontaneously develop something like a modern human language, nor do humans in the absence of social interaction.

Gene-Culture Coevolution

Genetically transmitted human traits and culturally transmitted linguistic traits coevolve at multiple levels. Early forms of communicative behavior may have introduced selection pressures on humans – if the new behavior improved our ancestors' fitness, for instance, by facilitating cooperation, biological traits that promoted learning, and using the system would be selected for, and spread in the population. This would result in an increase of linguistic skills in the population and in the production of more complex linguistic structures which, in turn, would pose further pressure on biological evolution (Deacon 1997; Dor and Jablonka 2014). Language is an important part of the human cultural niche, and as such it may continue to guide our evolution, as suggested by evidence for rapid recent selection for genes involved in cognitive and linguistic function (e.g., Dediu and Ladd 2007; Ayub et al. 2013).

Conclusion

The evolution of human anatomical and cognitive traits that underlie language probably started early in the *Homo* genus, in close interaction with demographic changes and other cultural developments, such as technology or art. The multiple interactions between cultural and biological traits suggest a coevolutionary history in which humans adapted to language as much as language adapted to humans. The evolution of imitation learning, whether in the vocal or the manual modality, provided a mechanism for social transmission that in turn enabled cultural language evolution: the generation and propagation of linguistic element such as phonemes, morphemes, or morphosyntactic rules and linguistic properties including combinatoriality, compositionality, or arbitrariness in populations of speakers.

In the face of a scarcity of direct evidence, studies of language evolution continue to gather evidence from a diversity of sources, from archaeology to genetics, to decipher the origin and evolution of the unique human skill that is language.

Definition

John Watson's experiment on children's conditioned emotional reactions

Introduction

In 1919, upon Watson's return from the army, he decided to pursue research, along with Rosalie Rayner, on children's emotional response and development based on conditioning processes. The first and only study that Watson and Rayner performed on this topic was the study with Albert B. or, most known, as Little Albert, at the laboratory of a hospital. This experiment became one of the most frequently cited in psychology books and magazines and is described as "one of the classic studies of twentieth-century psychology" (Todd 1994, p. 82).

The Conditions Surrounding the Experiment

Watson's academic career was built on examining animal learning. He was applying Pavlov's principles of classical conditioning, where innate bodily reflexes are conditioned with new stimuli to create new learning by association. Thus, conditioning causes events or stimuli to be associated in time, and learning takes place from the associated (simultaneous) arrangement of stimuli and responses. Watson concluded that the trial ends when the animal chooses the correct response.

The more often a response brings positive results, the higher the probability that it will be repeated by the animal (the law of frequency). Additionally, the animal will tend to repeat the most recent successful response (law of recency) (Hergenhahn 2000).

Upon his return from the army (1918) and before his abandonment of his academic career (1920), he decided to turn his attention to research on humans and especially on how conditioning processes influence human development. While teaching at Johns Hopkins University, he arranged to use a laboratory at Phipps Clinic (Moore 2017). Adjacent to Phipps Clinic was the Harriet Lane Home for Invalid Children, a hospital connected to the Phipps Clinic with a corridor (Watson and Rayner 2000).

Watson's interests centered on emotions; he considered emotions as mere physical responses, and he wanted to prove that emotional responses could be conditioned. For some (Rilling 2000) this was Watson's major contribution to learning theory and an explanation of phobic reactions through behaviorism. He believed that, since birth, infant humans have three unlearned emotional reactions: fear, rage, and love. Fear is evoked by only two stimuli that are unconditioned: a sudden noise and the loss of physical support but those fear-provoking stimuli are learned. Fear in infants can be observed in crying, breathing rapidly, closing their eyes, or jumping suddenly (Watson and Rayner 2000).

The Experiment

It is estimated that in early December 1919, Watson and Rosalie Rayner, his research assistant and later his wife, conducted a series of baseline trials. They chose only one child, Albert B., a healthy, well-developed, stolid, and unemotional child who cried rarely. He was raised almost from birth at the "Harriet Lane Home for Invalid Children" with his mother who was a wet nurse in the home. He had a normal life, and one of the main reasons he was chosen among other infants was that it was believed that the experiment could do relatively little harm to him. Different phases of the experiment were filmed. The experiment was

conducted, with the approval of Albert's mother, in a small, well-lighted dark room, and Albert was placed in a mattress, above a table (Watson and Rayner 2000).

Albert was assessed neurologically at around 9 months, in order to determine whether stimuli other than sharp noises and sudden removal of support can cause fear reactions. Thus, Albert was confronted suddenly with "a white rat, a rabbit, a dog, a monkey, masks with and without hair, cotton wool, etc." (Watson and Rayner 2000, p. 313); he showed no fear, at any time. Independently of the above observations, the experimenters tested whether the child would react to loud sounds by striking with a hammer a suspended steel bar three-fourths of an inch thick and 4 ft long; he reacted with fear and crying. Upon receiving the above results, Watson and Rayner wanted to examine the following: (a) if they could condition fear of an animal under the condition of visual presentation of the animal and simultaneously striking a steel bar, (b) if the conditioned emotional response established can be transferred to other animals or objects, (c) if time has an effect on the conditioned response, and (d) if they can devise methods for the removal of such conditioned emotional responses (Watson and Rayner 2000).

The experimenters had no other interaction with Albert until he became 11 months and 3 days old. He was presented with a white rat, and as he was reaching with his left hand for the rat, the experimenters were striking hard the steel bar behind his head. In the first trial, Albert fell forward and buried his face in the mattress. In the second trial, he jumped violently and began to whimper. A week later, he was exposed to the rat without the sound. Initially he did not reach for it, and when he did start to approach it with his hand, he withdrew it before contact, which indicated that the two joint stimulations of the first week were still effective. Albert had positive reactions to other objects by picking them up. In the next trials of the same day, the rat was presented in association with the sound, and Albert's reaction progressed from sudden bounce to turning away from the rat, then cringing his face and withdrawing his body to the left, and to falling to the right side and beginning to whimper and eventually

violently crying. Watson concluded that the conditioned fear response was completed (Moore 2017; Watson and Rayner 2000).

When Albert was 11 months and 15 days old, they wanted to examine whether the conditioned emotional response can be transferred for another object. Thus, they first presented Albert with different objects, and they noticed that he was comfortably playing with them that indicated that there was no transfer to other objects. When the rat presented alone, the child immediately began to crawl away from it and whimpered. Then, they presented a rabbit, and Albert had the same reactions as with the rat. When a dog was presented, similar reactions were elicited but not from the beginning of the interaction. He had similar reactions to a fur coat, cotton wool, a Santa Claus mask, and Watson's hair but not with other people's hair. Intermediate of the presentations with the aforementioned objects, Albert was presented with blocks, neutral objects that he happily played with throughout the experiment.

A week later, the rat was presented alone to Albert; he was cautious and was following it with his eyes, but he did not cry. As the rod was struck, his reaction was violent initially, but on the next two presentations of the rat alone, his reactions were as strong as before but without crying (i.e., crawling away from it). The experimenters also wanted to present the rabbit and the dog consecutively in connection with the sound of the steel bar and wanted to test whether Albert's reactions were similar in two different contexts, that is, the usual laboratory or a large, well-lighted lecture room. They found that the reactions were similar although less violent in the second room. From this phase of the experiment, they concluded that emotional transfer does take place (Watson and Rayner 2000).

At 1 year and 21 days old, upon Albert's exposure to the phobic objects, the conditioned emotional reactions by transfer persisted, although with less intensity. In the last phase of the test, they observed that when the child was under stress, he would thrust his thumb into his mouth, and he would become impervious to the fear earlier produced by the different stimuli. They suggested that the love stimulation one seeks

under the influence of harmful situations persists throughout life and could be described as a "compensatory" (and possibly conditioned) device, instead of the "expression of an original pleasure-seeking principle" as described by Freud (Watson and Rayner 2000, p. 316) Watson and Rayner did not have the chance to test for the effect of time on the symptoms or whether they could remove them because Albert moved out of the hospital soon after the last trial, but they contended that the symptoms would persist and modify personality throughout life.

Who Was Albert B?

Different researchers tried to discover the true identity of Little Albert. Some researchers (Beck et al. 2009) supported that his real name was Douglas Merritte, son of Arvilla Merritte who was working at the hospital at the time as a wet nurse. Douglas contracted meningitis from his aunt, developed hydrocephalus, and died from it at the age of 6. Fridlund, Beck, Goldie, and Irons (2012, as cited in Digdona et al. 2014) reported findings that Douglas had been neurologically impaired as early as the time the experiment was conducted. The general reactions from the above were that, if this was the case, Watson and Rayner's findings were challenged (Digdona et al. 2014). Other researchers (Digdona et al. 2014) concluded that the child was actually Albert Barger son of a 16-year-old mother by the name of Pearl Barger who was also a wet nurse working at the time at the hospital. One of the points for the defense of this opinion is that Watson typically used real names or initials of the infants he worked with; thus Albert B would be Albert Barger.

Ethical Concerns

Throughout the years, different publications challenged Watson's ethical standards, and some characterize Little Albert as a "victim" (Todd 1994, p. 85). Watson himself reported his hesitation in inflicting fear reactions to a child. His defense in continuing with the experiment was that Albert

was a strong, composed, unemotional child. Additionally, “such attachments would arise anyway as soon as the child left the sheltered environment of the nursery” (Watson and Rayner, 2000 p. 314). At the time, the Little Albert experiment did not raise serious ethical questions, although Watson warned his readers that for the replication of the experiment, considerable training was needed (Todd 1994).

Conclusion

John Watson and Rosalie Rayner planned to examine conditioned emotional responses on children. Specifically, they wanted to test whether they can condition fear reactions of different animals and objects to a 9-month-old healthy infant. The results confirmed most of the hypotheses of the experimenters but stirred up different reactions by researchers and the press for the ethical repercussions of conducting such a study to a child especially without extinguishing the symptoms evoked on the child.

Despite the questionable ethics and its methodological limitations, the Little Albert study (in reprint on Watson & Rayner, 2000) on conditioning became a “landmark” in behavioral psychology and changed the way we examine behavior and the way we practice. Furthermore, the results on fear acquisition and generalization initiated the development of treatments for phobias (Field and Nightingale 2009; Wolpe 1958 as cited in Beck et al. 2009) and other behavioral problems (Masters and Rimm 1987; Rachman 1997 as cited in Beck et al. 2009).

Definition

A group can be defined as at least two individuals of the same species staying together for an extended period of time and actively seeking each other out in order to interact.

Introduction

Many animal species, including humans, live in groups of varying size and composition. In order to understand how group living has evolved during evolution, one has to consider which benefits and costs that have led to this. If the costs have been higher than the benefits, it may have led to that a species has developed a more solitary life style. However, living in groups often gives advantages to individuals at different times of their lives, thus pushing animals to choose group living at some stages of their lives. It may also be that the environment and the available resources may differ in different areas leading to that individuals of the same species may choose to live solitary at times and in groups at other times. Humans show all sorts of constellations when it comes to living in large, medium, or small groups, as well as living solitary. Sweden, for example, has one of the highest number of solitary households in the world (<http://sverigesradio.se/sida/artikel.aspx?programid=2054&artikel=5615244>). The reasons can be discussed but having the economic possibilities to live alone can be one of the causes.

What Is a Group?

A group has been defined by Wilson (1975) as “any set of organisms, belonging to the same species that remain together for a period of time interacting with one another to a distinctly greater degree than other conspecifics.” Another definition presented is that “when two or more animals live together they constitute a social unit” (Lee 1994 in Krause and Ruxton 2002). Pitcher et al. (1983 in Krause and Ruxton 2002) assume that the interindividual distance between group members is a function of the trade-off between the costs and the benefits associated with group living, and this has been presented as “the elective group size concept.” This concept requires that animals are close enough from each other for continuous exchange of information, but this distance vary between species (Krause and Ruxton 2002). The animals need to be brought together by

social attraction by actively seeking each other out and not just due to the mere coexistence on the same spot due to access to feed or other resources (Krause and Ruxton 2002). As group behavior show a very large variation across and within species, it may be difficult to find one definition that fits all and Krause and Ruxton (2002) suggests to rather develop operational definitions that fits the study species and the framework of grouping.

It is not really possible to split animals into solitary living and group-living species, as this may differ over time (Krause and Ruxton 2002). Most species will be found together with individuals of the same species at certain times, for example, mother and young, during mating and during other times of their lives. The same species may also have different strategies regarding if it will live in a group or as single due to different circumstances. Singletons or very small groups have often been found when researchers have tried to screen group-living animals for group size. According to Krause and Ruxton (2002), “for many so-called group-living species the group size distribution can have a very wide range and usually will include many singletons.” This may also apply to humans, especially those living in cities, as humans tend to carry out different activities together without knowing each other, for example, training at the gym, watching a movie at the cinema, shopping, etc.

Is There an Optimal Group Size?

Many researchers have tried to find out if there is an optimal group size. However, as individuals in a group tend to have conflicting interests regarding group size, the observed group size is probably a compromise between the various interests (Wittenberger 1981). Wilson (1975) developed a model to predict optimal group size by plotting the separate effects of each selective factor affecting a particular individual's inclusive fitness as a function of group size. However, this method has been criticized by Wittenberger (1981) who means that the model is based on unrealistic assumptions. Another model by Wittenberger (1981) propose

that optimal group size for an average female is reached when the percentage change in mortality rate caused by adding one more individual to the group is equal to the percentage change in reproductive rate. The model predicts that in larger groups, mortality rate may decrease due to increased protection from predators but increase due to higher competition for resources or higher disease prevalence (Wittenberger 1981). Reproductive rate may increase due to offspring being safer in large groups and better fed but decrease due to poorer nutritional condition of females or more malnutrition among offspring (Wittenberger 1981).

Social living in vertebrates is predicted to have evolved in four different ways. The first case predicts that female survival rate increase with increasing group size while the reproductive rate decreases (Wittenberger 1981). An example of this is colonial living rodents who depend on mutual vigilance to detect predators and to dig burrow systems, but competition for food decreases reproductive output. The second case predicts that female survival rate decrease with increasing group size while reproductive rate increases (Wittenberger 1981). Two examples of this are elephants and gorillas where increased group size lead to competition within the group which reduce female survival, but at the same time, social defenses against predators increase offspring survival (Schaller 1963). The third case predicts that female survival rate and reproductive rate both increase initially with increasing group size, but a decline in reproductive rate limit group size (Wittenberger 1981). Examples of this are social ungulates and primates who form groups to get protection from predators, but competition for food limit group size (Geist 1971; Dunbar 1979). The fourth case predicts that female survival rate and reproductive rate both increase initially with increasing group size, but a decline in survival rate limit group size (Wittenberger 1981). An example of this is lions where cooperative hunting increase survival of both adults and offspring in small groups, but as group size increase, female mortality may increase while offspring still survive by suckling other females than their mother (Schaller 1972). Evolution of social living

in humans could have followed the third case as females may have increased their survival rate and reproductive rate by living in groups but access to food may have been a limiting factor.

How Dynamic Is a Group?

It is important to consider that every group of animals can be viewed as a separate population which is characterized by a birth rate, death rate, immigration rate, and emigration rate (Cohen 1969). If it is primarily the birth and death rates that determine group size, it should reach an equilibrium size that reflects the carrying capacity of the home range (Wittenberger 1981). If it is primarily immigration and emigration rates that determine group size, it reflects the adaptive choices and conflicting interests of group members (Wittenberger 1981). In open social groups, individuals can move in and out of the groups, and they do not associate with any particular individuals for longer periods other than their dependent offspring (Wittenberger 1981). In closed groups, individuals stay for longer times in the group.

How close individuals stay relative to other group members mainly depends on food abundance and predator pressure. Competition for food make the animals spread out, whereas predator pressure makes the animals come together. For example Gorillas, Cape buffalos, and Thomson gazelles usually remain in tight social groups when resting or having social interactions, but they spread out into looser groups when foraging (Schaller 1963; Sinclair 1977; Walther 1977). Stable groups may fragment into widely spaced subgroups, as, for example, lionesses that form stable prides that share a group territory, but pride members rarely hunt together as one group (Schaller 1972). Hyenas live on permanent clan territories, but members of each clan hunt alone or in temporary subgroups in the Ngorongoro Crater, whereas they do not defend clan territories or maintain clan integrity on the Serengeti Plains (Kruuk 1972). In hyenas group, size depends on prey size, and the hunting groups is adjusted to the intensity of competition (Kruuk 1972).

In chimpanzees, individuals may join or leave groups frequently with little signs of aggression (Lawaick-Goodall 1968). The social system in chimpanzees can be described as a large group or community comprised of individuals moving among many temporary subgroups (Lawaick-Goodall 1968). Within each group, individuals are familiar with each other and they may share a common home range (Kawanaka and Nishida 1975). Males roam throughout the home range and defend it from males of neighboring groups (Goodall et al. 1979). Females may occupy smaller home ranges and not visit all parts of the unit group range (Wrangham 1979). It may also happen that a female visit neighboring groups or that she moves over to a new group permanently (Nishida 1979). The formation of temporary subgroups in chimpanzees may be caused by the distribution of ripe fruits that they prefer as a food source and if the fruit is clumped or more spread out (Lawick-Goodall 1968). Long-haired spider monkeys that also eat predominantly fruits forage in small subgroups when the fruits are widely dispersed and in larger and relatively stable group sizes when the fruit occur in large localized clumps (Klein and Klein 1975). During other times of the year when the distribution of fruit is more varied, the group size of long-haired spider monkeys are intermediate and has less stable composition (Klein and Klein 1975).

Different Types of Group Living

There are different constellations of group living from pair to anonymous groups. For each group constellation humans may live in them during shorter or longer periods of their lives.

1. Pairs. Male-female, female-female, or male-male. The sexual system is usually monogamous groups for one breeding season or for life. It is often claimed that this is the traditional system that humans live under, but it may not be true for all cultures and places in the world.
2. Maternal groups. Several females of varying age staying together for extended times with

their young up to weaning or when young get into puberty. Often female young continue to stay in the maternal group while the male move away from their mothers group. The sexual system is polygynous groups where the males seek up the females for mating but live solitary or in all male groups for the remaining time.

3. Bachelor groups. Several males living together after having left their mother and the maternal group. This is usually performed by young males, but with increasing age they may become solitary.
4. Mixed gender groups. Both females and males live together in the same group for extended times. The groups may vary in size depending on species and environmental conditions.
5. Anonymous groups. Animals come together at feeding places or to get other resources, but there is no individual recognition or prolonged interaction between the animals. This is typical for schooling of fish or large flocks of birds. However, it also occurs frequently in human society when humans are travelling, shopping, or attending events.

Bases for a Functioning Group and Rank Order

A group is usually an actively formed and maintained unit of animals (Lindberg 2001) or humans. The cohesion of the group needs to be maintained and there are several different mechanisms to do that. Lindberg (2001) mean that “a major feature of the group is that each animal acts (or attempts to act) for its own maximum benefit in its interaction with conspecifics, and this may result in ‘emergent properties’ that affect the group as a whole, such as dominance hierarchies.”

Schjelderup-Ebbe (1935) was the first to study the dominance hierarchy by recording the pecking-order in chickens. Dominance can be explained as “the predictable relationship between a pair of conspecifics, where one animal has learnt to dominate the other (subordinate), which in its turn tends to avoid the confrontation” (Lindberg 2001). The animals need to have

individual recognition for this to work and they learn this relationship for future encounters (Lindberg 2001). When adding up all these dominance relationships in a group, one can talk about a dominance hierarchy, peck-order, or rank order. This dominance hierarchy is unique to each group of animals living together. If one individual disappear from the group due to actively leaving it, being pushed out, or removed from the group, or by death, then the equilibrium is temporarily upset until a new rank order has been set (Keiper and Sambrasus 1986). The rank an animal has in one group may not be the same in another group as dominance ranks are specific to a particular group.

In small groups of animals, the dominance hierarchy may be linear (Craig 1986), which means that the highest ranking animal (A) is dominant over the second highest animal (B), who is dominant over C and so on down to the lowest ranking animal. A dominance hierarchy can also be triangular, where A is dominant over B and C, but C is dominant over A. In a despotic dominance hierarchy, A is dominant over all other individuals, but they do not have clear dominance relationships. A complex dominance hierarchy means that there is not a clear pattern, but rather that each pair of animals within the group has a set dominance relationship. Based on the information of each pair of animals in a group, one can make a dominance index that can show which animals are the dominant, subordinate, and submissive in the group. This has been described in, for example, rats, cows, and other animals kept by humans. There is a lot of research on dominance hierarchies in domesticated animals kept on farms due to the animal welfare problems caused by not considering the problems with mixing animals into different groups of varying sizes. It is also worth mentioning that animals usually try to avoid conflicts with others in the group as this may cause injuries. This can be explained as the “avoidance order,” where subordinate group members avoid provoking those members above them in the rank order (Lindberg 2001). We do not usually talk about humans as having higher or lower dominance rank than other persons in a group, but detailed behavioral observations of a

group of humans would probably be able to identify persons with a higher or lower social rank.

Individual animals within a group may have different tasks depending on their rank. Both the dominant animals and the subordinate animals may be subjected to both advantages and disadvantages from living in a group (see benefits and costs of group living below). In nature, the juveniles usually have a low rank, but as they grow older, they may raise in the dominance hierarchy until they reach a high position. In some species, a top-ranking animal may keep its position just due to its old age, whereas in other species, younger animals may test the top-ranking animal in order to push it down from its position. This is usually happening between males in a group and less often in females.

In order for a group of individuals (animals or humans) to function, they need to be able to communicate. A common definition of communication is “the transfer of information from a signaler to a receiver.” Dawkins and Krebs (1978) argue that communication may be an attempt by the signaler to manipulate the receiver in order to increase its own fitness. This has led to the receiver being selected for its ability to find out which signals are honest and which are not, and thus it has created an arms race between signaler and receiver (Dawkins and Krebs 1978).

The type of communication also differs between species from visual, acoustic, chemical, and tactile to electrical. Humans exchange information also by written and electronic media (telephones, computers, internet, social media, etc.), which makes this dimension even more complicated.

Evolutionary Causes Behind Group Living

Natural selection is usually used to explain the evolution of different behavioral strategies in animals. Krebs and Davis (1993) mean that natural selection can only work on genetic differences, and therefore, the following three criteria must be fulfilled: (1) there must be, or have been in the past, behavioral alternatives in the population;

(2) the differences must be, or have been, heritable; and (3) some behavioral alternatives must confer greater reproductive success than others. When discussing how social living evolved in animals and humans, these criteria therefore need to be considered. Fitness can be explained as the reproductive success of an individual during its lifetime (Dunbar 1982). The more surviving offspring that reach reproductive age, the higher the fitness of the individual. However, as animals share genes with each other, fitness can also be increased by helping relatives to raise offspring. In social living, insects like termites, ants, bees, and some wasps evolution has even gone further so that only one queen in the nest is producing all the eggs and helpers at the nest take care of the eggs and feed the larvae. These insects are called eusocial animals and this is regarded as the highest classification of sociality. In mammals, the naked mole-rat (*Heterocephalus glaber*) and the Damaraland mole-rat (*Cryptomys damarensis*) are the only eusocial mammals currently known (Jarvis 1981). In the naked mole-rat, one female, the queen, and one to three males reproduce, whereas the others in the colony are workers (Jarvis and Bennett 1993). The other females are sterile, but if the queen dies, another female take over and become reproductive after competition among the females (Jarvis and Bennett 1993).

One can question why animals choose to help each other. However, when an animal is helping its relatives to survive and raise their offspring, an animal increases its probability to get shared copies of its own genes being passed into the future (Mendl and Held 2001). Hamilton's rule (1964) states that "the benefit to the reproduction chances of the helped relative, weighted by the probability that the relative shares the helper's genes, has to outweigh the cost to the helper's own reproductive success incurred through the helping" (in Mendl and Held 2001). Kin selection is when traits are promoted that increases the survival and reproduction of close relatives in addition to those of direct offspring (Maynard Smith 1964). Kin selection may be recorded by using inclusive fitness, which is an individual's own reproducing offspring plus the number of offspring of any

helped relative minus the help received by others to raise offspring (Hamilton 1964). This result in that animals should only help those individuals that it shares some genes with.

However, in some cases, animals also help those that they are not related to, i.e., shares genes with. For example, cooperation to defend resources increases the survival and reproductive chances of all involved. This type of mutual help is called mutualism, and it has been selected for because the fitness of all involved animals increase (Mendl and Held 2001). There are also cases when an individual animal help another animal at a cost to itself, but it does not receive any help in return until sometime in the future, and this is called reciprocal altruism (Trivers 1971). There are risks that helping another individual may never be paid back if animals are not meeting regularly. Therefore, reciprocal altruism has probably evolved when animals live in stable social groups and meet regularly over longer time periods (Mendl and Held 2001). One can summarize this part by proposing that evolution has led animals to cooperate in order to increase fitness, but in order for cooperation to be favored, it has been beneficial for animals to live in more permanent groups.

A review on social evolution in 217 primate species made by Shultz et al. (2011) found that closely related species have tended to organize their societies in the same way. The solitary foraging individual ancestors of primates started staying together as multimale and multifemale aggregations around 52 million years ago, when the ancestors of monkeys and apes split off from the ancestors of lemurs and other prosimian primates. At this time, primates became more diurnal and started to hunt during day time and Shultz et al. (2011) suggest that staying in groups could have decreased the risk of being killed by predators. Today, chimpanzees and baboons live in this type of mixed sex groups. However, gorillas live in harems with one male and multiple females and the New World titi monkeys live in pairs. Living in harems or pairs is a derivative from a second stage of the evolution of sociality in primates occurring 16 million years ago (Shultz et al. 2011).

Humans are suggested to have lived in groups since they occurred as *Homo sapiens* around 200,000 years ago (Roberts 2011). Ancestors to them, *Homo neanderthalensis* (lived 350,000–28,000 years ago), have by archeologists been suggested to have lived in family groups where the males stayed in the family they were born in whereas the females moved to other families when they became adults (Roberts 2011). Human evolution involves the occurrence of at least eight different species during the last two million years, but it is difficult for archeologists to reconstruct how they lived socially. The archeological findings from *Homo sapiens* have shown that as hunters and gatherers they lived in smaller groups that could aggregate to larger groups when there was plenty of food in smaller areas (Roberts 2011). After the last Ice age (11000–4000 years ago depending on place on earth), *Homo sapiens* settled down in more restricted areas and started to grow the land and keep animals. Creating villages with groups of humans living together then became more and more common. Today, millions of people may live in the same city, but then individual recognition is no longer possible.

Benefits and Costs with Group Living

There are many benefits of group living, which may explain why living in groups developed for so many species of animals, including humans. A suggestion of these benefits based on Krause and Ruxton (2002) are:

- Antipredator: many eyes, encounter-dilution, predator confusion, predator swamping, selfish herd effects, defense against parasites, communal defense, predator learning
- Foraging: group hunting, coarse-level local enhancement, public information, information center
- Mate choice
- Keeping warm (heat): reduced heat loss, protection from desiccation
- Reduced cost of transport (movement): in air, on the water, under water

Mendl and Held (2001) suggest that the benefits of group living are:

- Foraging: increased efficiency in detecting, acquiring, and defending food
- Predation: avoiding predation by detection, dilution, and defense
- Thermal regulation in endotherms: especially, small homeotherms can conserve energy by huddling together

Coalition formation in social primates could be another benefit of group living (Dugatkin 1997).

Concerning why early humans started to live in groups, it has been suggested that foraging was one important reason (Roberts 2011). By hunting in groups, they could catch and kill larger prey than one human could manage.

For some species or some individuals of a species, it may be better to live solitary due the costs of group living. A suggestion of these costs based on Krause and Ruxton (2002) are:

- Competition for resource, when more individuals share a finite resource there will be less for each individual.
- Loss of food due to theft by other group members, i.e., kleptoparasitism.
- Aggression between members of the group due to other reasons than foraging.
- Pseudo-interference, i.e., reduced foraging efficiency in individuals that are forced by competition to use poorer feeding sites.
- For sessile foragers, the path that mobile food takes to them can be blocked by the presence of another forager.
- Individuals get in each other's way.
- Prey animals may detect a group of predators more easily and take more effective evasive action.
- Predators may preferentially target larger groups of prey.
- Confusion or interference between fleeing individuals may increase the success rate of predators with increasing prey group size
- Area-restricted search tactics by predators are effective against grouped motionless prey.

- Risk of misdirected parental care when breeding animals are closer to each other.
- Risk of transfer of pathogens when individuals are in closer proximity to each other.

Mendl and Held (2001) consider that some of the following factors may be a disadvantage for group living in animals:

- Resources have to be shared with other group members and defense of resources is negative.
- Groups of animals are more conspicuous both when they are prey animals and predators.
- Increased risk of contact-transmitted parasites.
- Cuckoldry through fertilizations of extra-pair males.

Living in groups may have facilitated the development of more complex social behaviors such as alloparenting, social learning, and helper systems, but we do not know which of these that have been involved in the evolution of group living and which are a consequence of group living (Mendl and Held 2001).

Important Consequences of Group Living for Cultural Development

When animals live in groups, they can learn from each other. This has been called “cultural transmission,” and it can be defined as “the transfer of information from individual to individual through social learning or teaching – both within and between generations of animals (Bonner 1980; Boyd and Richerson 1985). One famous example of cultural transmission is the Japanese macaque monkey “Imo” who learned to wash sweet potatoes to get rid of the sand and where her peers and relatives via social learning also developed the same washing behavior (Kawamura 1959; Kawai 1965). According to (Dugatkin 1997), “Cultural transmission involves a model individual and an observer who learns a specific behavior or response from the model”. If the animal does not learn anything, such as during local enhancement or social

facilitation, it is not cultural transmission. In humans, cultural transmission occurs through social learning and teaching. The main difference between learning by an individual animal or human and cultural transmission is that the latter may be passed on through several generations. This may also be one important reason for why humans evolved and were so successful on our planet (for an overview of human evolution see Roberts 2011).

There are many other areas related to social living in animals and humans that could be discussed, as, for example, social facilitation, synchronization of behavior, learning to interact socially with others, and all aspects of learning in animals that involves transfer of information between group members. Overlapping generations that occur in many animals may also help in the transfer of knowledge from one generation to the next generation. However, the scope of this chapter was to describe different aspects of why animals and humans are living in groups, and I hope the many different aspects of this have been clarified.

Conclusion

Living in groups has evolved through generations because individual animals and humans have benefited from it regarding foraging, reproduction, survival, climatic protection, learning, and for other reasons. In order to manage group life, communication between animals and humans has evolved, and it has been adapted to the species and different circumstances. However, there are also costs of living in groups such as competition for food, reproductive partners and other resources, negative effects of low dominance, increased risk of disease and other risks for the health, and welfare of individual animals and humans. Therefore, animals and humans may choose to leave the group if the cost is higher than the benefits. In human culture, there are so many other aspects of group living which do not occur in wild animals, so one has to be very careful when trying to interpret human behavior in the light of evolution.

Local Mate Competition

► Local Sex Ratio

Local Sex Ratio

Veronica Kraft and Aurelio José Figueredo
Department of Psychology, University of
Arizona, Tucson, AZ, USA

Synonyms

Local mate competition

Definition

Ratio of males to females in a local subpopulation, which is not compared to the entire possible population *or* the measurement of females compared to males within a limited sample of a population based on a fixed vicinity relative to the species).

Introduction

Sex ratio is the proportion of males to females in a population. It is often studied on large scales and examined to make inferences concerning an entire population. When examining sex ratio on a localized, specific scale, it is important to recognize the differences between these populations to help indicate what could be causing the variability within different subpopulations of the same species. Genetically speaking, sex ratio should be consistent throughout the entire species and try to achieve a 50/50 balance. But nature is not perfect; external factors from the environment

hinder this balance. Local sex ratio is the measure of those subpopulations of a species, and the “local” is relative to that species and cannot be considered a constant. Fisher’s sex ratio theory explains this in relative cost and gain principles. If there are more females in a population, then it would be in the better interest of the mother to invest more in available males to mate with the abundant females. Similarly, if there are more males in a population, then it would be in the better interest of the mother to invest more in available females to mate with the abundant males. This will eventually lead to a sex ratio of 50:50 in outbreeding populations. However, there are exceptions to this principle. The number of daughters or sons that are born or those that make it to reproduction can be altered in multiple ways. Some, but not many, can control for this through manipulating genetic factors. Species that utilize the method genotypic sex determination (GSD) have sex assignment completely dependent on the genotype – assigned at fertilization (Cook 2002). Environmental sex determination (ESD) is a bit more common but also more easily studied and observed. Species that utilize this method use factors in the immediate environment or the predicted future environment to determine the sex very early in development or decide to foster the well-being of one sex over the other (Kraak and Pen 2002). They will invest in the sex that has a higher propensity to reproduce in the current environment or possibly in the future if predicted conditions are correct. Both methods of sex determination, even genotypic, respond to the proximate vicinity of the individual and the conditions within their niche and usually these mechanisms often coincide. Regardless of how it is achieved, local sex ratio is influenced by some outside factor – be it available mates, temperature, or resource allocation.

Changing Local Sex Ratio by Genotype at Fertilization (GSD)

Different species can determine sex ratio *prior* to birth based on environmental and local factors. These factors may include the number of males or females already present in the population, how

many of those individuals are viable, or resource availability. At fertilization, in most cases, it is the mother that will determine the sex of the offspring, basing her decision on the previously mentioned factors. Various species have been shown to control for sex at conception or during development, primarily insects, such as the common housefly (*Musca domestica*) and the parasitic wasp (*Nasonia vitripennis*).

Controlling of Local Sex Ratio in the Parasitic Wasp *Nasonia vitripennis*

The parasitic wasp (*Nasonia vitripennis*) will alter the sex ratio based on local mating competition. The female wasp will survey the area by detecting chemical signals left by any previous females and will estimate the number of males present in the local region where she will lay eggs – and where her offspring will eventually breed. If the female plans to lay eggs in a host that has been previously parasitized (superparasitized), then she may select to reproduce more males to compete with those males that were previously born. Ultimately, this is to the mother's advantage because if she has more sons that are viable available for hatching females to mate with, there is a better chance that her genes will be replicated (Werren 1980). There are also other factors that could affect the female's bias towards sex. Shuker et al. (2006) found that the emergence time of other broods by other females and the number of other parasitized hosts on the same patch both influenced a female wasp's sex ratio decisions when laying her own brood. These are seen as two other ways that the female is optimizing the chances that her sons will be able to compete with other local mates. The female parasitic wasp is surveying her surroundings and adjusting the sex of the offspring accordingly from the genotypical level, which results in an adjusted local sex ratio for that given population of parasitic wasps.

Changing Local Sex Ratio by Environmental Factors (ESD)

While some species may use the current environment and local population to make assign sex to offspring genetically, others have to leave the

influence towards sex determination to the environment. In these cases, environmental factors, such as latitude, temperature, and air/water composition, will influence the predetermined sex of offspring. Conditions may favor more male development due to signaling that this sex is more viable in these conditions, prompting female offspring to change sex. There are various species, primarily amphibian and reptilian, that practice this type of sex determination.

Influence of Latitude and Water Temperature on the Atlantic Silverside (*Menidia menidia*)

The Atlantic Silverside has a genotype that is acted on by two factors – genetics and environment. The temperature of the water will alter the predetermined sex. This mechanism can be compared between schools found in different latitudes within the same waters to show a difference in sex ratio between cooler and warmer water temperatures compared to those found at a midpoint between the two extremes. Lagomarsino and Conover (1993) examined families within schools of Atlantic Silverside from Nova Scotia and South Carolina to grade how temperature altered sex ratio among these populations. Those in the cooler waters near Nova Scotia saw little influence on sex determination from water temperature, with only 1 of the 23 families examined showing an effect from the cooler temperature. The families in South Carolina (low-latitude population) saw an extremely significant sex determination factor due to water temperature. South Carolina is of a lower latitude which promotes higher water temperatures; all families examined were influenced by these higher water temperatures, which is evident through their sex ratio favoring males and consisting of almost no females. A majority of families in the low-latitude population showed evidence of a shift in sex ratio, suggesting that latitude, and the corresponding water temperatures, causes genetic differences of sex determination. Water temperature plays a major factor due to natural selection – favoring the most “fit” sex to better enhance sexual reproduction. Temperature in the larval developmental stage appears to affect the length of the gestation period – the first born are female, and the second are males. This causes a difference in body size that later on will favor the

female for reproductive success, thus affecting sex ratio (Lagomarsino and Conover 1993).

Temperature-Sensitive Sex Determination in *Emys orbicularis*

The turtle species, *Emys orbicularis*, shows an interesting case of where the sex ratio is affected by the genome as well as directly by the environment. Genes may determine the sex of offspring but that is then limited by influence from the environment through temperature. Entirely phenotypical females will be born when temperatures are above 29.5 °C, whereas entirely phenotypical males will be born when temperatures are below 27.5 °C, regardless of genotypic sex determination. Sex differentiation appears to take place at 28.5 °C, indicating that this intermediate temperature favors the original sex genotype (Zaborski et al. 1988). This is due to the H-Y antigen found in the blood for females being expressed only at certain temperatures regardless of genotypical sex determination (Zaborski et al. 1982).

Changing Local Sex Ratio After Birth and Partial Development

Many species do not have direct influence over the genetic sex determination of their offspring, and therefore, they influence the sex ratio by adjusting care and resources towards the more viable sex. This decision is based on factors within the environment (unpredictability) and resource availability. In an unpredictable environment, one sex may be favored over the other, with the decision of which sex depending on the species. The decision then influences parental investment – resources may be given to one sex over the other due to the environment favoring the vitality of that sex or by practicing brood reduction, focusing on reduction of the less viable sex. In the case for resource allocation, parental investment of resources goes towards one sex over the other, leading the other sex to be negatively influenced.

Brood Reduction and Sex-Biased Provisioning in the Zebra Finch and Crimson Rosella

The crimson rosella (*Platycercus elegans*) will be selective towards the sex that will have the highest

reproductive success in the given, or future predicted, environment. In most cases, this is usually the female chick. Female crimson rosellas usually favor female offspring for the first hatching, causing the sex ratio to be particularly biased towards females. Krebs et al. (2002) found that this is most likely because females can breed within the first year of life and males cannot, making the female chick more immediately successful. Young female crimson rosellas are also a bright green color for their first year of life, making them an easy target for mating. The color may be correlated to reproductive potential; the lighter color being a sign to potential mates that this specific female is young, and therefore may not have hatchlings and most likely has a high reproductive potential. Krebs et al. found that adult males were more likely to breed with subadult females and the opposite, young males with older females, was never the case. An adult female would be biased towards hatching female chicks first to increase her chances of genetic replication through offspring, another cost, and benefit scenario. With all this considered, we can assume the bright green plumage of a young female is acting as a result of sexual selection. It was also hypothesized that male chicks were more common later in the hatching season to eliminate sibling competition between sons (males cannot breed till at least 2 years of age). So, if a male was born early one season and a male was born late in the same season, the younger one would have mate availability disadvantage in the future, and the two sons would ultimately compete for mates. This may also be because males are heavier and mature more quickly, making them costlier than females (Krebs et al. 2002). There are some studies showing that it is possible that available resources greatly affect which sex is provisioned over the other, mainly depending on resources and food supply (i.e., water, seeds availability, seed quality, etc.), especially in zebra finch populations (Burley et al. 1989). The zebra finch (*Taeniopygia guttata*) is a species of bird shown to change the sex ratio through sex-biased laying sequences followed by possible brood reduction. Clotfelter (1996) hypothesized that brood reduction took place through sex-biased provisioning from either parent towards a specific sex, which usually showed

through a father bias for sons. In most cases, this can result in a higher mortality rate of one sex, although in this specific zebra finch population, Clotfelter did not find a bias mortality rate for either sex. The one thing that was noted in this study was that there were more sons born at the beginning of each season, which is suspected to be a retaliation towards inevitable predation – if they have more sons, when a majority die from predators they will still have sons left to reproduce and carry on the family genes. This is most likely a result of the unpredictable environment that these birds tend to inhabit.

Impact on Local Sex Ratio by Experienced Environmental Factors

Humans, similarly to some birds, may select for one sex over the other by using a method of reduction. The Trivers-Willard hypothesis suspects that in times where resources are plenty and the future reproductive stage for offspring looks bright, parents will invest more into their male children. Contrarily, if resources are scarce and future reproductive climate is unpredictable, parents may decide to invest more towards their female children. If resources are available to invest into the child, males are selected for as a “bang for your buck” – males can have more offspring compared to females, which increases the likelihood that the parents’ genes will be replicated. Even with this as a consideration for males, both males and females are limited to the number of offspring they can have in a lifetime, and therefore it is not worth the investment if resources are limited and the environment unpredictable. A study by Davis et al. (2007) showed this phenomenon but only among impoverished Hispanic-Latino populations in a general sample of mothers in Southwestern Arizona. The mothers in this sample were more likely to invest in their daughters when resources were limited, which was indicated by what they regarded as a healthy body size and weight for male compared to female babies. These biases are subconscious and subtle but in some cases may be more severe if negative environmental factors are a heavy influence.

Conclusion

A sex ratio measurement will often times vary among a species based on location but ultimately will work towards achieving an even ratio. While environmental factors may indicate fitness strategies that may increase reproductive success, the genes will always still play a part. In conclusion, every species is attempting different fitness tactics to reach an even ratio of males to females to overall increase the fitness of the entire species – this is just easier said than done, which is why local populations work with what is in the immediate environment.

Local Sexual Practice

Yan Wang

Department of Psychology, Fudan University, Shanghai, China

Synonyms

[Sexuality in community](#); [Sexuality in neighborhood](#); [Urban sexuality](#)

Definition

Sexuality under norms of a neighborhood or community, including socio-sexuality and adolescent sexual onset.

Local sexual practice, including individual's sexual attitudes and behaviors, could be shaped by many factors, among which local norms and early family environment constitute the two most vital influencing variables.

Norms and Local Sexual Practice

Quite a lot of research indicated Local norms, especially the peer norms, usually exert important

influences on individual's sexual activities. For example, by interviewing with a sample of community young single men, one study (Jacques-Tiura et al. 2015) showed men's sexual violence could be predicted powerfully by the peer group norm that encourage sexual aggression. Another research (Santana et al. 2006) showed adherence to traditional masculine norms would influence men's condom using behaviors.

Actually, the essential role of context on individual's sexual activities has been supported by lots of literature. Based on the multilevel and longitudinal data, research (Browning et al. 2005) showed socioeconomic features of neighborhood context that could exert significant effects on adolescents' sexual activities. Under the context of neighborhoods with low collective efficacy, such as economic disadvantage, residential instability, and racial-ethnic heterogeneity, those who experienced low levels of parental monitoring would show especially high levels of early sexual activities. In addition, a recent research (Kaczkowski et al. 2017) demonstrated that young male who attended to diverse social groups showed a lower level of sexual violence and the effect of social group diversity on men's likelihood to commit sexual violence was partially mediates by male's hostility directed toward women.

The deviant behaviors usually result from the overestimation of the prevalence of these behaviors. One study (Martens et al. 2006) indicated participants tend to overestimate the occurrence of sexual behaviors among their peers. Another research (Kilmartin et al. 2008) also pointed out college males tend to overestimate the level of others' sexism and underestimate their tolerance with sexism. As a result, many social norms-marketing campaigns, which aim at correcting participants' misperceptions by informing them the proper information, have been carried out to reduce individual's deleterious behaviors.

For example, by correcting the cognitive distortions one intervention study (Kilmartin et al. 2008) indicated the level of male's negative attitudes toward female decreased significantly. Another program (Gidycz et al. 2011), which combines social norms and bystander intervention education, found university men in the

intervention program showed a lower level of negative attitudes and behaviors toward sexual aggression compared with those in the control group. Other program (Leone et al. 2017) also supported the important roles of peer norm and bystanders in preventing sexual aggression.

Life History Theory and Individual's Sexual Behavior

According to the Life History theory, in order to pursue the optimal trade-off choices, organisms tend to adopt different life history strategies varying on a slow-fast continuum. People adopting faster strategies would prefer engaging in sexual activities at earlier age, having more sexual partners and building less stable pair bonds (Belsky et al. 1991).

In line with life history theory, one study (Belsky et al. 2012) with large samples demonstrated two dimensions in the environment, harshness and unpredictability, could uniquely predict participants' accelerated life-history strategy, which particularly referred to number of lifetime oral sex and sexual intercourse partners. Based on the longitudinal data, another research (Dishion et al. 2012) also demonstrated that disadvantaged family background at early age predicted powerfully individual's fast strategies, such as early sexual activity, number of partners, unsafe sex, and number of pregnancies or children, through the enhanced role of deviant peer group around them. Other research (Browning et al. 2005) also found parental monitoring would influence girls' timing of first intercourse significantly.

According to paternal invest theory, Draper and Harpending (1982) pointed out the absence of father in early life could exert a vital influence on girl's reproductive strategies. They stated that father-absent females would believe that male parental effort was not essential to reproduction. They would show early expression of sexual interest, engage in sexual activities at earlier age with less discrimination, and also showed poor ability to establish long-term and stable relationship with man. Most importantly, they also stated the timing of pubertal maturation for the father-absent girls would be accelerated.

Conclusion

Local sexual practices can be shaped by local norms and family background at the same time. Individuals usually overestimate the occurrence of deleterious sexual behaviors around them and underestimate the level of their actual sexual activities. By delivering the proper information, the interventions aim at correcting individual's perception and then reducing the level of the deviant behavior. Many intervention programs exhibited ideal effects. In line with life history theory, the existing literatures supported disadvantaged family background at early age could facilitate the selection of fast reproductive strategies, which put the individual at a high level of risk to commit deleterious sexual behaviors. The father-absent girls tend to adopt fast reproductive strategies.

L

Definition

This chapter delineates loneliness as a universal human condition through the lifespan. This construct is discussed as an individual difference and as a human condition, and explores its evolutionary beginnings. Finally, loneliness is presented as a defining quality of online interactions in the digital age, from chatrooms of the twentieth century to modern-day social networking sites. This chapter concludes with a tentative answer to the decades-old question of whether loneliness is amplified in the digital age.

Introduction

Loneliness may be defined as the distress resulting from a cognitive discrepancy between ideal or desired social relationships and the reality of those relationships. That is, loneliness is experienced when an individual’s connections with friends, family, or romantic partners are less

satisfying than what is desired. The roots of loneliness reach deeply into the very fabric of our society and its constituents – the individuals who conflate isolation and physical removal from others with shame, failure, and rejection. Sadler (1978) wrote that:

we live in a world that is on the move, where people regularly leave loved ones or are left behind. We experience drastic changes that often contribute to the loss of important attachments. We witness regularly the breakup of marriages and families, of communities and neighborhoods, of friendships and working relationships, of organizations and partnerships. (p. 157)

The societal response to these dissolutions forms society’s basic understanding of the phenomenon of loneliness.

Although frequently confounded with isolation or alienation, this phenomenon stems primarily from an individual’s *perception* of his or her integration with a group, rather than the reality. Sadler states that this perception is multifaceted, encompassing the five dimensions outlined in Table 1.

In recent decades, loneliness researchers have continued to operationalize this construct along distinct dimensions that capture its multifaceted nature across social, familial, and romantic domains. Table 2 outlines several commonly used loneliness scales, their distinct dimensions, and example items for each.

Across these widely published and validated scales, it is readily apparent that loneliness is often conceptualized within social psychological literature as an unhappiness with friendships, familial relationships, or romantic relationships;

however, these scales do not tap into the precipitators of – or inclination toward – the experience of this unhappiness. Loneliness may exist as one of two phenomena: (1) a temporary condition brought about by significant life changes (e.g., job loss, relationship conflict) or (2) a more persistent or chronic experience, in which an individual experiences a long-lasting isolation from human contact or socialization. This will explore loneliness as both an acute individual difference and a chronic condition, as an evolved adaption, as unique experiences of loneliness across cultures, and as it exists in a digitally connected world.

Loneliness as an Individual Difference

Because loneliness emerges due to a variety of causes and at different life stages, it is considered a unique individual difference that may appear in many forms across individuals. For example, poor physical or mental health is linked with higher levels of loneliness, whereas individuals of higher socioeconomic status and non-single marital status typically report significantly lower levels of loneliness (Skaff 2008). Furthermore, involvement in organized group activities and higher contact with close relatives are associated with fewer loneliness experiences.

However, many such demographic dimensions may stem from life choices (e.g., physical health, group activity involvement) or life stage (marital status), rather than more stable and unavoidable individual differences. Two such differences on which loneliness might differ are delineated below: gender and age.

Loneliness in Modern Life, Table 1 Sadler’s (1978) five facets of loneliness

Interpersonal	Awareness of separation from individuals
Social	Awareness of being divided in loyalty between competing groups
Cultural	Alienation, anomie
Cosmic	Estrangement from total unity of existence
Psychological	Natural sense of separation stemming from biological individuation

Gender and Loneliness

For decades, a wealth of literature has cited that females from school age to adulthood report higher levels of loneliness than their male counterparts (e.g., Skaff 2008). This is particularly the case when considering females’ higher proclivity toward emotional distress and perceived interpersonal isolation. Whereas females tend to report loneliness as it relates to social domain – friends, acquaintances, and colleagues – males

Loneliness in Modern Life, Table 2 Commonly used loneliness scales

Scale	Number of items	Dimensions	Example items
UCLA loneliness scale	20	Intimate others Social others Affiliative environment (i.e., belonging)	How often do you feel that there is no one you can turn to? How often do you feel that people are around you but not with you? How often do you feel that your relationships with others are not meaningful?
De Jong-Gierveld loneliness scale	28	Deprivation Abandonment Missing companionship Sociability Meaningful relationships	It makes me sad that I lack companionship There is no one who shows a particular interest in me
Social and Emotional Loneliness Scale for Adults (SELSA)	37	Social loneliness Emotional loneliness: Family Emotional loneliness: Romantic	I have friends that I can turn to for information (R) I feel close to my family (R) I have a romantic partner with whom I share my most intimate thoughts and feelings (R)
Differential loneliness scale	60	Romantic-sexual loneliness Friendship loneliness Family loneliness Loneliness in groups	No one in the community where I live cares much about me A lot of my friendships ultimately turn out to be pretty disappointing

(R) denotes a reverse-scored item

show a stronger relationship between loneliness and social experiences with parents and family members. Social network analyses have found that the density (i.e., cohesiveness and interconnectedness) of a social network predicts loneliness only in males, whereas *quality* of dyadic relationships – rather than clusters or groups of individuals – tends to be more important for females.

Age and Loneliness

A wide body of research has found a positive relationship between age and loneliness across the lifespan, with more than a third of older adults in the USA experiencing loneliness. McInnis and White (2001) recorded spoken descriptions of loneliness experiences among widowers living in a senior citizens' apartment complex. The authors clustered over one thousand meaning units into major themes, in which loneliness (1) occurred as a result of the absence of important relationships (i.e., social loneliness described above, or the missing companionship dimension of the de Jong-Gierveld Loneliness Scale)

and (2) accompanied the lost connection with loved ones, both alive and deceased. Old age in particular precipitated a state of anxiety, fear, and sadness stemming from increased dependency on others throughout daily life, which led many individuals to feel as if they were suffering silently, unable to verbalize their loneliness for fear of increasing their burden on others.

But although loneliness is widely perceived as a problem of old age, a growing body of empirical literature suggests that adolescence is the peak age for experiencing loneliness. Adolescent bullying and victimization are widely considered a leading explanation of this trend, and such bullying has been shown to continue to predict loneliness into adulthood (Segrin et al. 2012). Additional factors linking youth and loneliness are depression, low socioeconomic status, proclivity toward aggression, and difficulty with social skills. However, most characteristic of teenage years is the perceived need to conform with peers – a need that is linked with strong experiences of loneliness during this life stage in particular.

Lastly, loneliness can exist as a property of the organization, rather than exclusively of the individual. During the occupational life stage (i.e., post-college and pre-retirement), employees may experience workplace loneliness due to the perceived inadequacy of interpersonal relationships with colleagues and other professionals (Wright 2015). In addition, due to the closely tied nature of most workplaces, loneliness can spread in a contagion effect beginning with a single openly lonely individual. Research has not yet demonstrated a link between loneliness in the workplace and in adolescence or older adulthood.

Loneliness as a Chronic Condition

Loneliness does not exist solely as an acute individual difference but also as a more permanent experience traversing many life stages due to underlying conditions. Loneliness has been associated with mental illness and anxiety (Cacioppo and Patrick 2008) and has been shown to underlie aggression, domestic violence, murder, post-traumatic stress disorder, and suicide. Lonely individuals are more likely to be high in negative affectivity, to act in a socially withdrawn fashion, and to lack trust in the self and others around them. Furthermore, these individuals tend to feel little control over their success or failures and report low satisfaction with personal relationships.

As was stated at the beginning of this , loneliness as a construct is often confounded with the simple state of being isolated or alone; however, when considered as a chronic condition, it is especially necessary to view it as a series of psychological responses to the state of isolation. There is a crucial distinction between the *painful* and the *enriching* dimensions of being alone, depending solely on how the individual chooses to interpret his or her isolation. As such, these chronic precipitators of loneliness should be considered as related phenomena, in which chronic anxiety, depression, negative affectivity, and social withdrawal may be linked with a proclivity toward interpreting isolation in a negative, rather than positive or enriching, fashion.

Antidotes to Loneliness

Not surprisingly, loneliness has become a symbol of depression in global societies – a precursor for agoraphobia (i.e., the extreme fear of public places) or social anxiety. Because it has been linked with mental illnesses and harmful or unhealthy behaviors (e.g., smoking, addiction), loneliness has become synonymous with an aberration or mental disorder – a shortcoming, rather than a human experience. It could be argued that loneliness is – and has always existed as – a universal human condition of varying degrees of severity.

In turn, Mijuskovic argues that loneliness is closely tied with consciousness, in that conscious awareness of the sources and signs of loneliness may help inform individuals of how to avoid isolation and seek social contact. It is through a conscious evaluation of the lonely experience that individuals may partake in any given “antidote” to loneliness, such as seeking a sense of belonging, togetherness, or intimacy with one or more people. This search for belonging is often fostered by empathy as a driving force of connection with other people – that is, sharing lived experiences with family or friends who understand loneliness as a universally shared condition.

The drive to avoid loneliness in search of intimacy and social proximity is possibly the most powerful psychological need of human beings and may have remained so for hundreds of thousands of years.

Loneliness in Evolutionary Beginnings

Loneliness may be considered an individual’s natural response to particular situations across the lifespan, rather than a sign of weakness. Indeed, scholars who support this idea cite a wide array of findings that point toward an innate, biological, and possibly adapted aversion to loneliness and social isolation.

In an illustrative study of the *ball toss paradigm*, Zadro, Williams, Sommer, and colleagues instructed participants to take part in a three-person activity in which they were to toss a ball back and forth with two group members.

Unbeknownst to the participant, his or her fellow group members were confederates instructed to follow a prearranged script, in which after several rounds of ball tosses, the confederates exclude the participant by only tossing the ball between each other. Regardless of self-esteem and personality attributes, the researchers found that participants responded within only a few minutes with negative affect, predominately with anger and sadness. Notably, female participants sought to regain a sense of belonging upon being isolated, demonstrating higher nonverbal engagement with the confederates. Male participants, on the other hand, sought to regain self-esteem by disengaging more quickly and appearing disinterested in the game (Zadro et al. 2004).

The ball toss paradigm has since been replicated in an online environment, in which participants were instructed to toss a ball between two other players, who were believed to be actual participants on other computers but were, in fact, programmed players. fMRI results suggest that even when participants are told that their group members are programmed, responses to social isolation are far from trivial: Researchers found that the emotional region of the brain that is activated in these paradigms (i.e., the dorsal anterior cingulate) is the same region that responds to physical pain (Kawamoto et al. 2012). In other words, the physiological response accompanying the experience of loneliness and isolation mirrors that of actual harm. Further research in this area has illustrated that even innocuous and brief examples of ostracism – and, indeed, even by despised others (with whom the individual logically should *not* desire close contact) – are related to physical pain and psychological distress, possibly because humans have evolved to accurately detect and avoid ostracism.

Further evidence of physiological responses to loneliness are evident in DNA and mortality research. A meta-analysis of findings related to loneliness and mortality found that actual and perceived social isolation are associated with an increased risk for early mortality (Holt-Lunstad et al. 2015), although it remains unclear whether perceived (but not actual) social isolation may be linked with a proclivity toward negative affect,

depression, and social anxiety which may, in turn, partially account for this finding. In addition, the mere experience of social isolation has been found to impair DNA transcription in human immune cells, which disrupts thinking, willpower, and perseverance, as well as the ability to read social signals and monitor social skills (Cacioppo and Patrick 2008).

This process, in which social isolation begets loneliness and loneliness inhibits social abilities, is a well-studied finding encapsulated within the self-perpetuating cycle of loneliness and depression (Kenrick et al. 2014), as illustrated in Fig. 1.

This seven-staged cycle shifts from (1) the mere experience of loneliness to (2) a heightened uneasiness around others, particularly those with whom a close relationship has not yet been established (i.e., acquaintances, new partners, coworkers). To circumvent this discomfort, individuals begin to (3) avoid social contacts, and when avoidance is impossible (e.g., in the workplace), unappealing behaviors may surface during interactions – behaviors that, in the modern day, one might refer to as “social awkwardness” stemming from socially evoked anxiety. Among individuals who are aware of this increase in social anxiety, (4) self-defeating thoughts ensue – thoughts that reinforce their fears of loneliness and isolation – which, over time, transform into (5) the experience of depression. Not only does depression predict chronically low mood and (relatedly) low affect, but it also predicts low energy or interest in pursuing sociable activities. It is at this point in the cycle that one witnesses a direct relationship from perceived isolation to active avoidance of social contact, and it is this evasion of contact that predicts (6) negative interpersonal behaviors such as rejection of attempted contact, outward displays of irritation or anxiety, and expressions of guilt, shame, or hopelessness when with others. As a result of these negative interpersonal behaviors, (7) social contacts often begin to avoid the individual, which only furthers (1) the original feeling of loneliness – and thus the cycle continues in a downward spiral.

Returning to the argument posed by Cacioppo and Patrick (2008), however, such a cycle need not be explained exclusively in psychological

Loneliness in Modern Life, Fig. 1 The self-perpetuating cycle of loneliness and depression

terms; in fact, a key argument in the evolutionary realm might suggest that the impairment of DNA transcription occurring in even the earliest stages of this self-perpetuating sequence may jointly contribute to the cycle's later stages.

An Ultrasocial Species

The question that then begs to be asked revolves around the role of loneliness in the human experience. If one were to argue that loneliness is an evolutionarily adaptation, what must follow is a broad understanding of the functions it serves in specific habitats. Cacioppo and colleagues argue for one such example, in which social-environmental factors such as low social support trigger an evolved aversive signal, which draws attention to the varied social risks that loneliness might pose. This signal is particularly important when faced with situations across the lifespan that require social support, such as early and end-of-life dependence on close others. Among mothers, the absence of social support may result in a shortage of child-rearing options or might limit access to food, shelter, and protection from harm during early motherhood. In support of this argument, experimental manipulations of loneliness have yielded an increase not only in depressive symptomatology but also perceptions of unsafety: In times of loneliness, fear and decreased self-esteem jointly predict a heightened caution of

perceived threats in the surrounding environment. Self-esteem in particular is a noteworthy association with loneliness due to its function as a gauge of exclusion and self-confidence, variables that are intricately tied with modern-day conceptualizations of loneliness and isolation.

What follows from this key argument is an *evolutionary model of loneliness* (Cacioppo and Patrick 2008), which argues that when an individual experiences loneliness, a feeling of unsafety should ensue due to an anachronistic survival mechanism that intensifies sensitivity to social hazards. Humans are, in every sense of term, an *ultrasocial species* in the sense that collaboration and cultural identification (e.g., with norms, conventions, institutions) are remarkably strong influences on the ways that humans relate to one another. This ultrasociality is important because for evolutionary ancestors, survival did not necessarily depend on brute strength but rather on the ability to form bonds and collaborations with others; the idea of “strength in numbers” is personified in humankind’s ancestral past. The literal, physical pain associated with loneliness may, therefore, trigger a fear response so disruptive in everyday functioning that it urges the individual to avoid loneliness and seek sociality, no matter the outcome.

A question that might logically follow this insight is why, if ultrasociality was a key ancestral

goal, ostracism existed at all. Many evolutionary theorists have suggested that humans, like social animals including bees, ants, and primates, use ostracism as a tool for social control. Ostracism and social isolation therefore manage deviant or troublesome members of the group by motivating such members to obey norms and contribute to the broader collective. Should these members respond to ostracism with a drive to reaffiliate with the group, the final outcome would be a positive one: Group strength would increase as a product of cohesiveness and the pursuit of a common goal. As such, one component of Cacioppo and colleagues' evolutionary model of loneliness is called the *reaffiliation motive* (RAM), which represents an individual's motivation to reconnect with others – a motivation that is often triggered by perceptions of social isolation.

The Heritability of Loneliness

A second argument for an evolutionary understanding of loneliness revolves around the theorized heritability of loneliness. Researchers have argued that heritability can differ by environment, individual differences such as age or gender, and genetic predisposition to loneliness; furthermore, the expression of genetic factors associated with loneliness may change over the lifespan, potentially accounting for differences observed between children and older adults (Cacioppo and Patrick 2008). Goossens et al. (2015) argue that several genes may account for loneliness, either through immune system functioning or the expression of particular neurotransmitters. Regarding the immune system, past research suggests that the human body functions less efficiently among lonely individuals – an indicator of an impaired or weakened immune system. Furthermore, receptors – chemical substances that are sensitive to a particular neurotransmitter or signaling substance (e.g., dopamine, serotonin) – of *oxytocin* have been linked with prosociality, trust, and social awareness. As such, the oxytocin receptor gene reflects qualities not often seen in lonely individuals as per the evolutionary model of loneliness (i.e., high sociality, trust, social awareness) and therefore stands as a promising genetic marker of the expression of loneliness. Returning to an

earlier mention of social-environmental factors (e.g., low social support) that may trigger feelings of loneliness, it would therefore follow that gene-environment interactions might lead genetically predisposed individuals to feel an increased sense of loneliness when exposed to hostile or isolated situations.

Loneliness and Attachment

Also contributing to the heritability argument of loneliness is the oft-cited link between loneliness and *human attachment styles*, distinct classifications of dynamic long- and short-term interpersonal relationships. These classifications stemmed from a classic study in 1978, when Mary Ainsworth separated infants from their mothers and observed their reactions to the presence of a stranger and, subsequently, to their mother's return. These observations distinguished three clear patterns of response: (1) secure, in which infants respond with minimal distress to a mother's absence and warmth to her return; (2) preoccupied, in which infants remain anxious upon her return, as though wary of future abandonment; and (3) avoidant, in which infants display little emotional response to either stranger or mother.

In the decades since, psychologists have hypothesized that attachment behaviors characterize and define human beings from the cradle to the grave – that is, attachment to primary caregivers might generalize to other prominent relationships formed throughout the lifespan, including adult friendship and romantic love. An attachment relationship is, therefore, an enduring social relationship underscored by expectations of responsiveness and support, which mutually provide confidence to explore and develop independence throughout the lifespan.

To summarize attachment theory, secure, preoccupied, and avoidant attachment styles differ along two key dimensions: anxiety and avoidance. Table 3 illustrates these distinctions, further separating Avoidant attachment by low anxiety (dismissive; the disinterest in social contact) and high anxiety (fearful; the active fear of social contact). Not coincidentally, loneliness has been tied to both anxiety and avoidance, as was

Loneliness in Modern Life, Table 3 Dimensions of human attachment styles

	Low anxiety	High anxiety
Low avoidance	Secure	Preoccupied
High avoidance	Avoidant (dismissive)	Avoidant (fearful)

illustrated in Fig. 1 and which furthermore may stem from gene-environment interactions. It would appear, therefore, that loneliness has roots in childhood and early attachment processes – a theoretical mediation effect in which attachment styles and cognitive mechanisms may partially account for the relationship between loneliness and basic attachment theory.

Supporting a theory of parent-child origins of loneliness, researchers have found that peer attachment strongly mediates the relationship between parental attachment and loneliness (Bogaerts et al. 2006), in which parental attachment – known to influence peer and romantic attachment styles later in life – thereby plays a role in an individual’s experience of loneliness. Although one study found no direct relationship between parent and child loneliness, the researchers did observe a decrease in peer-evaluated cooperation skills among daughters of lonely parents. This decrease, in turn, predicted higher levels of loneliness (Junttila and Vauras 2009). Similarly, Henwood and Solano (1994) found that parents’ loneliness negatively impacts children’s use of relationship-enhancing strategies, such as a willingness to attribute positive factors to a partner’s disposition, and negative factors to the broader situation at hand.

Historically, loneliness has been linked with attachment styles across the lifespan as a function of attachment insecurities (i.e., anxiety and avoidance). High attachment insecurities have been associated with low levels of trust, relationship satisfaction, and closeness – factors also tied with loneliness as per the evolutionary model of loneliness. Laboratory studies of social interactions have found that individuals high in attachment insecurity tend to engage in interactions that are lower in intimacy and warmth (Black and

McCartney 1997). As such, it could be stated that the instability of personal relationships among insecurely attached individuals is closely linked with the subjective experience of loneliness. Furthermore, children of parents who socially isolate themselves or are unresponsive to the needs of family members (i.e., symptoms of loneliness) are more likely to develop such attachment insecurities early in life, thereby contributing to a chronic level of vulnerability to loneliness.

Summing across extant literature on the underlying genetics of loneliness, a question that therefore begs to be asked is whether loneliness is actually inherited. Although certain gene expressions may predict a proclivity toward trust and sociability – qualities lacking among chronically lonely individuals – it is clear that environmental characteristics also play a key role in the development of loneliness early in life. Next is presented a body of literature that considers loneliness as a cultural phenomenon, moving from potential gene-environment interactions to a determining factor that is predominately environmental.

Loneliness Across Cultures

A *culture* is defined as an amalgamation of characteristics that not only influence the attitudes, beliefs, and behaviors of a particular social group (e.g., geographic, ethnic, socioeconomic) but that also give unique meaning to various life experiences. Often, cultures are defined through geographic boundaries as a simple function of mobility: Historically, social groups remained relatively isolated from one another with the exception of trade and conflict. In their isolation, these social groups shaped norms, traditions, and values that collectively formed distinct cultures, which set them apart from other groups. Although genetic expression may be highly correlated within any particular group, the cultural environment itself poses many influences on the physical and mental attributes of its members.

Regarding loneliness in particular, Yang and Victor (2011) found that the country in which a person lives shows a greater impact on reported

Loneliness in Modern Life, Fig. 2 Johnson and Mullins' (1987) comparative perspective of loneliness

loneliness than age, which has proven a significant predictor for decades. Whereas Northern European nations (i.e., Scandinavia, Ireland) report the lowest levels of loneliness (i.e., accounting for 6% of individuals), citizens of Russia and Eastern European countries show the highest levels (10–34% across age groups).

One potential explanation for cross-cultural differences in loneliness may stem from a theory posed by Johnson and Mullins (1987), displayed as a process model in Fig. 2. This comparative perspective model outlines a process in which cultural values lend themselves to the development of – and proclivity toward particular – personality structures, which in turn predict expectations of social interactions. The first sentence of this defined loneliness as the distress stemming from a discrepancy or mismatch between an individual's ideal social relationships and the state of his or her actual relationships. Should a person hold high expectations of what constitutes friendship or romantic relationships, and should these expectations not be met (i.e., a deficit in the quality or quantity of a person's desired sociality), loneliness may ensue.

Johnson and Mullins therefore conceptualize a *loneliness threshold* or the minimum level of social contact that an individual requires to *not* feel lonely. The lower the threshold, the higher an individual's proclivity toward loneliness; and should a culture emphasize high expectations of social interactions, members of that culture may be at a heightened risk for experiencing loneliness across the lifespan. Indeed, hypotheses of cultural incongruity support this perspective, in which members of one culture may experience loneliness due to high exposure to a second culture with a different loneliness threshold. More specifically, industrialization itself might explain the curiously high levels of loneliness among elders of recently industrialized cultures. Cultural

ideals of privacy, which have stemmed from Western ideology, may be jarring to members of older and more remote generations. There is, for example, no natural word for “privacy” in Russian: As Eastern European countries have adapted to Western ideals in the past century, increasing levels of loneliness among older generations may be partially explained by this disconnect between old and new.

As such, in the consideration of cross-cultural differences in loneliness, future research should examine the factors that predict social satisfaction as it relates to culturally defined social ideals. Specific to Russia and Eastern Europe, which report the highest levels of loneliness currently on record, researchers cite the dramatic sociopolitical changes that have taken place since the late 1980s as one key cause. For one, younger generations have been encouraged or even forced to emigrate to more prosperous countries, leaving family and friends behind in pursuit of a career. Those who are left behind may consequently report higher levels of loneliness, as has been found among the elderly in China (Yang and Victor 2011). For another, with sociopolitical and economic changes come transformations in the mere definition of social relationships, including expected norms, behaviors, and values. Disconnects with these newly developed social norms may lead to a sense of cultural isolation or ostracism, which may in turn predict loneliness.

Although cross-cultural research on loneliness is sparse beyond Western borders, much research has investigated *hikikomori* in Japan, a phenomenon of extreme social isolation spanning months or even years. Hikikomori, which describes both the social isolate (i.e., as a human) and the social condition of isolation, has been found to stem from dismissive-avoidant attachment styles, oxytocin levels, low social skills, lack of perceived social support, and – in some cases – the

occurrence of a stressful event, lending further credence to the argument for genetic predispositions toward loneliness (Teo et al. 2014). Similar cases of severe self-prescribed isolation have also been documented and researched around the world, including South Korea, France, Oman, Spain, and the USA – countries whose expectations of social relationships may engender distinct loneliness thresholds that have yet to be studied empirically.

Next the impact of a particular form of culture on the expression and experience of loneliness must be considered – namely, *digital culture* or the culture that emerges from the use of information and communication technologies (ICTs).

Loneliness in the Digital Age

It could be argued that the evolutionary purpose of speech has, throughout history, been the formation and maintenance of social intimacy. The mere act of speech with others allows humans to learn about social contacts and whether they are worthy of trust and collaboration. Social conversation, therefore, has been a cornerstone of community and social organization since the emergence of human life.

However, humans now live at the precipice of a social world that is changing rapidly, and theorists from Sherry Turkle to Clay Shirky now posit that

ICTs are beginning to eclipse human pillars of social intimacy. Such theorists – whether they be cyberpsychologists, cyberneticists, or philosophers – now state that humans are less emotionally fulfilled and more isolated by the same ICTs that have promised for decades to bring them together. (Even so, it deserves noting that Locke predicted the invention of voicemail to be a key culprit in this transition, a prediction that has yet to be realized.) These scholars state that society runs the risk of depersonalization due to an excess of information available at every moment – information that provides human-to-human conversation without necessitating face-to-face contact.

Since the introduction of ICTs into daily life, many have wondered whether the digital age would pose more benefits or detriments to loneliness, social isolation, and mental health – that is, whether online connection would drive down offline connection. This question illustrates the *Internet paradox* (Kraut et al. 1998) or the phenomena by which the Internet is largely used for social interaction but has also been linked with social isolation (i.e., the lack of social interaction), and – among heavy users – depression. In this section, the relationships between loneliness and the Internet, online communication more broadly, and social networking sites (e.g., Facebook; see Fig. 3) are discussed, as well as competing models of Internet use and loneliness.

Loneliness in Modern Life,
Fig. 3 Specification of levels of ICT use

Loneliness and the Internet

As was illustrated in Table 2, the Social and Emotional Loneliness Scale (SELSA) differentiates between social loneliness (i.e., missing companionship) and emotional loneliness (i.e., the inadequacy of familial or romantic relationships). Researchers who have applied the SELSA to Internet users have found that high levels of Internet use are associated with low levels of social loneliness, possibly because such use fulfills these social needs; however, high levels of Internet use are also related to increased emotional loneliness, possibly because those who invest exaggerated amounts of time on online friendships have neither time nor resources to invest in offline relationships.

On the one hand, researchers have found a significant positive correlation between loneliness and Internet use among college students, with males reporting higher Internet use and higher loneliness (Hughes 1999). This relationship is exaggerated among students reporting excessive Internet use, compared with those who exhibit more moderate levels of use. On the other hand, sheer hours of Internet use had no impact on loneliness over time, but rather psychological dependence on the Internet. As such, it is evident that the Internet itself is not harmful, but is rather a tool; heightened compulsions or neediness related to the online world as an escape may be symptoms of related, but separate, conditions (e.g., Internet addiction).

The question that therefore begs to be asked is whether the origin of loneliness – online as opposed to offline – plays a role in Internet use. Odacı and Çelik (2013) found that loneliness while offline does not predict problematic Internet use and, furthermore, this loneliness is not necessarily predictive of social interactions online. In fact, one study found that individuals who score higher on loneliness are more likely to use the Internet for computer-based entertainment and to obtain information about the entertainment world (Whitty and McLaughlin 2007). As such, loneliness while offline might beget – or at least not contest – loneliness online among individuals who use this social tool for predominately informational purposes.

Loneliness and Online Communication

With regard to the Internet as a social tool in particular, a notably smaller body of research has investigated the relationship between computer-mediated communication and loneliness. Although no relationship has been demonstrated between mobile phone use and loneliness among average users, research has pointed to a mediation effect in which loneliness partially accounts for the relationship between social support or social skill deficits and cell phone addiction (Jin and Park 2013). However, Hu (2009) has noted a temporary increase in loneliness after chatting with others online compared with individuals assigned to engage in face-to-face interaction; furthermore, this effect was exaggerated among individuals with high trait loneliness. A second study followed up on these findings by distinguishing between the target of communication as a stranger or known other. In a sample of middle school students, no relationship was observed between online communication and loneliness when communicating with strangers; but contrary to expectations, researchers saw a negative impact on loneliness when chatting with familiar others (e.g., classmates, friends; Li et al. 2013).

This finding may be partially explained by research conducted by Ong et al. (2011), who found that students who spent more time chatting with familiar others online exhibited greater familial loneliness (i.e., as per the SELSA) due to reduced time spent in familial relationships. However, these individuals showed decreased romantic loneliness due to the increased ease of maintaining romantic relationships online, even in the absence of face-to-face contact. Indeed, loneliness may be a byproduct of excessive ICT use because time investment in online relationships comes at the expense of offline relationships.

There are, however, situations in which online communication may pose more benefits than detriments between friends. Internet use may allow anxious children and adolescents to fulfill critical social interaction needs through self-disclosure in an online, physically removed setting that might otherwise feel too threatening in the physical world.

Loneliness and Social Networking Sites

As social networking sites (SNS) such as Instagram and Sina Weibo have reached an alarming percentage of the connected world, research on the effects of SNS use on a plethora of psychological variables has also increased at a rapid pace. Regarding loneliness and self-disclosure in particular, individuals scoring higher in loneliness tend to be more likely to disclose personal and relationship information online, whereas those lower in loneliness tend to disclose personal views (Al-Saggaf and Nielsen 2014). This distinction may be due to a deep-rooted fear of disclosing potentially objectionable opinions and driving away social contact, whereas fact-based information may foster connection without risking objection. Furthermore, lonely individuals on Facebook often engage in positive self-disclosure less but negative self-disclosure more, often in hopes of engendering socially supportive responses from contacts (Jin and Park 2013). Lonely individuals therefore view Facebook as more useful for self-disclosure and social connection than individuals who are not lonely, but their satisfaction while on Facebook is often lower than that of their counterparts – possibly due to a heightened focus on negativity while engaging with friends. Lastly, individuals with access to the Internet but *without* a Facebook account tend to score higher on loneliness; whether this difference is an indication of causal effects or individual differences remains to be investigated.

Although a wealth of research has linked passive Facebook use (i.e., scrolling through news feed) with social comparison and lower self-esteem, much less research has investigated the link between SNS use and the related, but distinct, variable of loneliness. Below, this body of work is separated by the relationship (positive, negative, or neither) demonstrated between SNS use and loneliness.

SNS use increases loneliness. Supporting the argument that SNS use increases loneliness, Schwartz (2011) did indeed observe a positive relationship between loneliness and both Facebook use and Facebook posting behaviors among college students. However, self-esteem

may have confounded this relationship (i.e., due to its historically strong positive relationship with loneliness): Schwartz also found that college students with low self-esteem posted more frequently on Facebook and used Facebook for longer periods of time, while also attributing Facebook more heavily as a key presence in their social lives.

A 2010 survey of more than 1,000 individuals yielded more mixed findings: Although users who engaged in directed interaction with friends (e.g., wall posts, direct messages) reported lower levels of loneliness, those who engaged in passive use without engaging in interaction were more likely to report increased levels of loneliness (Burke et al. 2010). Contrary to expectations, lonely individuals tend to have more Facebook friends than those who are not lonely, possibly as a form of compensation for perceived deficits in offline sociality.

SNS use is not related to loneliness. In a meta-analysis of almost 9,000 individuals across 18 studies, Facebook use did not adequately explain variation observed in loneliness (Song et al. 2014). This null effect is worthy of note due to its lack of bias toward any particular sample characteristic (e.g., college setting, age, ethnic breakdown), researcher bias, or validity of the operationalization of ICT use or loneliness. When averaged together, the *lack* of a signal (in either direction) should be telling.

SNS use decreases loneliness. Lou (2010) found that Facebook intensity may reduce perceived levels of loneliness, regardless of motive for using Facebook (e.g., social, informational); furthermore, both Facebook intensity and motive for use were associated with increased offline friendship.

It is important to note that the research cited above is cross-sectional – that is, causality cannot be inferred based on a positive or negative relationship alone. Whether lonely people are drawn to Facebook or Facebook actively causes loneliness is a distinction that cannot be made through correlational methods alone. However, in 2013, Deters and Mehl experimentally manipulated Facebook use to observe changes in loneliness that could conclusively be attributed to SNS use.

Half of participants were randomly assigned to post more heavily on Facebook than usual, while the other half were given no instructions regarding Facebook use. The researchers found that individuals who posted more frequently exhibited reduced loneliness, partially due to an increase in social connection. This decrease in loneliness remained a robust finding independent of whether individuals had received direct social feedback from friends online.

Competing Models of ICT Use and Loneliness

With the exception of Deters and Mehl (2013), a vast majority of the previously cited research has been unable to tease apart causality due to exclusively correlational methods. Although a few scales have been developed to measure loneliness as it relates to the online world (e.g., the Virtual Environment Loneliness Scale, see Table 4; Usta et al. 2014), most studies have paired responses to inventories such as the UCLA Loneliness Scale with self-report measures of Internet and Facebook use (e.g., *How many hours per week do you use the Internet?*) – a methodology that may yield misleading results due to social desirability biases (e.g., a hesitation to report very high levels of use or loneliness), inaccurate memory for use, or differing definitions of what constitutes Internet or Facebook use (e.g., e-mail, text messaging, Messenger as a distinct entity from Facebook).

Loneliness in Modern Life, Table 4 The virtual environment loneliness scale (translated from the original Turkish)

Dimension	Example items
Virtual socialization (Sanal Sosyalleşme)	I have a lot in common with the people around me when online When online, I feel in harmony with people in my social circles
Virtual sharing (Sanal Paylaşım)	I'm much more comfortable online than in real life I trust my online friends more than my friends in real life
Virtual loneliness (Sanal Yalnızlık)	Nobody knows me very well online I find it difficult to express myself online Compared with the real world, I am often misunderstood online

A second problem with many studies previously reported is an underlying assumption that Internet users are a homogenous group, without taking individual differences into account. Amichai-Hamburger and Schneider (2014), for example, cited personality as a key variable in which SNS use might differ: Mirroring their offline reality, introverts tend to have smaller social networks online compared with extroverts; however, they also take greater care in tending to their online profiles. To their benefit, introverts often find ways to compensate for their social preferences through online communities, including leveraging asynchronous communication to avoid the potentially tiring impact of face-to-face, synchronous contact. Furthermore, social anxiety may act as a confounding variable in the relationship between loneliness and preference for online social interaction; although such a preference may be linked with loneliness, it may also be a function of the social anxiety demonstrated by lonely individuals.

To address these gaps in extant literature, there exist two competing models of Internet use and loneliness that draw this distinction, examining whether lonely people use ICTs differently, or whether ICTs cause loneliness. More specifically, Kraut et al. (1998) argue that Internet use leads to loneliness, whereas Amichai-Hamburger argues that lonely people tend to spend more time online. The latter of the two groups of researchers causally tested both models, in which (A) neuroticism (as one key personality factor) leads to social use of the Internet, which leads to loneliness or (B) neuroticism leads to loneliness, which leads to social use of the Internet. Of the two models, model (B) emerged significant, suggesting more conclusively that lonely people tend to use ICTs more heavily, especially among women.

This study was among the first to challenge the (still predominant to this day) notion that ICT use predicts loneliness in the digital age, regardless of the prevalence of correlational research supporting this claim. These contradictions are succinctly demonstrated in one study by Morahan-Martin and Schumacher (2003), who found that although lonely individuals used the Internet and e-mail with higher frequency, they

were also more likely to use the Internet to secure emotional support; although these individuals were more likely to make friends online and, what's more, to report higher satisfaction with those friends, they were also more likely to use the Internet as a means of modulating negative mood. Finally, and as a result of their motives for Internet use, lonely individuals were more likely to report that their Internet use – although supportive, although friendly, and although satisfying – caused disturbances in their offline functioning, such as interfering with social activities and work.

This compilation of findings summarizes many key points made by decades of research on the issue: Although it does not appear that ICT use causes loneliness, it is difficult to say conclusively that lonely people are more strongly drawn to ICT use. Future research must first take into account the varying effects of individual differences, gene-environment interactions when interacting with the online world, and attachment-related predispositions toward loneliness. Although there are certainly situations in which Internet and SNS use may ameliorate the negative effects of loneliness – for example, fostering social connection even in the absence of face-to-face contact – there are also situations in which ICT use may worsen these effects, as in the case with heavy use and replacement of offline relationships for online interactions.

Conclusion

To conclude, therefore, research suggests that ICTs are nothing more than a tool for communication that is best used in moderation. Although lonely individuals may enhance and expand their social network through online communication, it is also possible that extended time spent on ICTs will limit the ability to enhance existing offline ties. Moving forward, this body of research would benefit from shifting from a predominately cross-sectional methodological base to an experimental or longitudinal focus to better understand the causal effects of loneliness on ICT use and, in some situations, the effects of ICT use on

loneliness. Furthermore, research beyond Western borders is immensely scarce: To be able to make cross-cultural comparisons, researchers must first explore the relationship between ICT use and loneliness in nations or social groups where both variables – whether operational or psychological – may appear and manifest entirely differently. Finally, researchers should consider the use of ICTs to combat experiences of loneliness across age groups and backgrounds; the structured use of social networking sites, online communication venues, and the Internet in general may help ameliorate the negative impacts of loneliness within specific populations that are more vulnerable to depression, anxiety, or ostracism.

This has discussed loneliness in its most basic form as defined by societal aversions to alienation, loneliness as both an individual difference and a chronic condition, and loneliness as an evolved adaption and product of cultural variation. Stemming from this prerequisite discussion, correlational, experimental, and meta-analytic research has been presented that underscores loneliness as it exists in the digital age – an age of sociality and solitude, of connection and isolation. Although it may be a stretch to state conclusively that human-kind now exists “alone together,” it is certainly possible that technology may – in some forms and for some individuals – magnify the experience of social isolation. But it is equally possible that technology can form relationships where there were none that it can foster friendships that would otherwise have been impossible given predispositions toward loneliness, social anxiety, or self-doubt. Wherever technology may drive people apart, it also has the unique power to drive them together; and for those most in need of social connection, it may have a substantial amount to offer.

Definition

Long-term memory is thought to be of unlimited storage capacity and can hold information for a very long time.

Introduction

The ability to learn and remember is essential for survival. Over the course of an organism's life, numerous events take place that have an impact on both the organism, its expectations for the future, and its ability to thrive. Although cases of tremendous ability to remember events have not been associated with great fortune or happiness (Parker et al. 2006), memory is an integral part of our personalities and our life stories. In this section, the nature of long-term memory (LTM) will be discussed in relation to the modal model of memory (Atkinson and Shiffrin 1968). It is now established that LTM is not a unitary structure in which all information is kept, but that it is a very diverse system involving different types of information and various brain areas (Squire 2004). Research has shed light onto the characteristics of the different types of memory as well as the mechanisms involved in the creation and maintenance of LTM.

The Evolution of Long-Term Memory Through Time

Perhaps the most influential model of memory was the modal system of memory proposed by Atkinson and Shiffrin (1968). This model proposed that memory can be broken into different types, based mainly on the duration of the information being held. Thus, three types of memory were proposed: sensory, short-term, and long-term memory (LTM). Sensory memory lasts for only a few seconds and reflects the registering of a stimulus on our sensory organs. That stimulus may be a sound (echoic), an image (visual), or odor (olfactory) but quickly this stimulus decays. Short-term memory (STM) as was initially proposed was the next unit of the modal memory system, where information entering through the senses was maintained for processing for a limited period of time (seconds to minutes) and then would either be stored in LTM or decay. Of particular importance for STM were processes such as rehearsal which would enable the transfer of that information into LTM. Once information is stored in LTM, it will be kept for ever and it will be available for retrieval, if the appropriate cue is used (Shiffrin and Atkinson 1969).

Research has contributed to the emergence of a new way of understanding STM which is rather different from the proposed model (Atkinson and Shiffrin 1968). New evidence gave way to a more complex and more elaborate model of STM, termed working memory (WM), which shifts the emphasis from the maintenance of information for a short period of time to the manipulation of information involving different modalities (Baddeley and Hitch 1974; Baddeley 2000). One may wonder if any changes have occurred and whether our understanding of LTM has progressed in any way that is parallel to the developments made in STM.

It turns out that plenty has changed in our understanding of LTM which seems to be more complex than it was originally believed. It is now established that LTM is not a unitary construct but a rather diverse memory system, involving different types of information supported by multiple brain areas (Squire 2004). The main distinction between

the various types of LTMs is between declarative (or explicit) and nondeclarative (or implicit) type of memories. These two main types can also be distinguished further so that declarative memory can be distinguished into semantic memory, such as memory for a particular topic, i.e., the planets and the galaxy, or episodic memory, such as events associated with a place and time, i.e., attending a concert last year. Non-declarative memory can also be distinguished into different subtypes of memories such as those associated with skills (procedural memory) such as knitting or riding a bicycle, priming (responding faster to previously seen information even if we report not noticing it) or learning that is associated with classical conditioning such as reacting in a fearful way when a bee is approaching, after being stung by one.

Although these types of LTM are all “created” equal at the molecular level (Bailey et al. 1996), they are different in many other ways, as studies have shown in the last 50 years or so. In fact, different types of memories seem to be stored in different parts of the brain so that declarative types of memories are associated with activation in the temporal lobe (hippocampus, subiculum, and entorhinal cortex), whereas nondeclarative memories are associated with activation in areas which were active during learning, such as the basal ganglia (Squire 2004).

The most famous patient in the area of memory or even neuroscience in general is probably Henry Molaison, although he is familiar to all as H.M. (Tonegawa et al. 2015). H.M.’s bilateral temporal lobectomy by the neurosurgeon William Scoville treated his epilepsy but rendered him unable to retain information for more than a few seconds and thus he was unable to form new memories, a phenomenon known as anterograde amnesia. Brenda Milner, the neuropsychologist evaluating H.M. post-surgery, noticed this amazing phenomenon which gave much insight and sparked many research questions as to the role of the hippocampus in learning and memory. The absence of the hippocampus did not affect old (remote) memories and H.M. could recognize people from his past, but amazingly, he could no longer memorize new information and seemed to have lost recent memories. His case was in accordance with other

instances of head injury which have demonstrated that memory loss happens in a distinct fashion, so that more recent memories are more fragile and thus more likely to be lost in an event of injury or disease, compared to older memories, a characteristic known as graded amnesia (Winocur et al. 2013). However, H.M. was capable of learning other tasks such as the procedural task of mirror drawing albeit in the absence of his conscious recollection. Thus, H.M. would practice and improve on this task, but he was unable to recollect having done it before, demonstrating that this motor skill, a procedural type of memory is supported by brain areas other than the hippocampus and so it remained possible even following the bilateral temporal lobectomy (Josselyn et al. 2017; Tonegawa et al. 2015).

This phenomenon of dissociation between old and new memories is rather interesting. How are older memories different from recent memories and why is the hippocampus important? On the one hand, recent memories tend to be richer in terms of episodic information associated with an event. Learning new information is accompanied by details such as perhaps the time of day and the place in which learning took place, but over time, these episodic details tend to fade and what eventually remains in LTM is the main information or the “gist” as it is usually referred to (Feld and Born 2017; Payne et al. 2009).

The main mechanism that differentiates new memories from old is consolidation. Consolidation is the process that takes place in the brain in order to solidify new information and render it stable or capable of withstanding a long period of time without getting lost or erased (McGaugh 2000). Thus, recent memories are more fragile, because they haven’t had the opportunity to become consolidated yet. The process of consolidation was initially proposed by Müller and Pilzecker in 1900 (see review by McGaugh 2000) and it is now known to be consisted of two different types or phases. Synapse consolidation (or fast) and systems consolidation (or slow) (Dudai et al. 2015). Synaptic consolidation takes place at the level of the neuronal synapse and it involves changes in firing of the neurons

involved, such as long-term potentiation (LTP), gene transcription and translation, branching and sprouting within a short period of time following acquisition or learning. Systems consolidation, on the other hand, may take much longer to be completed (days, months, or even years), and it involves reorganization of several cortical areas that participated in the new learning so that these areas can be involved in supporting this learning in the future, thus, LTM (Dudai et al. 2015).

Consolidation mainly takes place during sleep (Pavlidis and Winson 1989; Wilson and McNaughton 1994). More specifically, consolidation of declarative memories seems to benefit from slow wave sleep (SWS) whereas non-declarative memories seem to benefit from rapid eye-movement (REM) sleep (Karni et al. 1994; Gais et al. 2000), although consolidation seems to be occurring also in quiet wakefulness, at least in animals (Diba and Buzsáki 2007).

The area of the brain in which consolidation takes place at least at the beginning or right after acquisition seems to be the hippocampus but this does not mean that the memories are stored in the hippocampus itself. The most accepted hypothesis regarding the locus of memory consolidation is known as the standard model of consolidation which argues that the hippocampus is needed in order for new information or new learning to be established and subsequently its role becomes less important (Frankland and Bontempi 2005). This model is challenged by evidence which argues that perhaps this may not be the way that consolidation works for all memories and that perhaps the hippocampus is also necessary for the subsequent retrieval of episodic memories even if they have been acquired a long time ago, known as the multiple trace consolidation hypothesis (Nadel and Moscovitch 1997).

The idea of a physical trace of memory existed since ancient times, with Plato using the analogy of a wax impression to refer to memory. It wasn’t until the beginning of the twentieth century that the German Zoologist Richard Semon revived this idea of a physical trace of memory and coined the term “engram” to refer to it and he proposed that once this engram is formed, it

remains dormant until it can be awakened by the presentation of information similar to the one which was present when the memory was initially formed (acquisition or encoding) known as “ecphory” or retrieval (Josselyn et al. 2017). But perhaps the person who popularized both the term and the idea of the engram was Carl Lashley (Bruce 2001). Known more for his failed search for the engram, Lashley pursued the engram by lesioning the cortex of animals in order to isolate it and to be able to show that it existed. Partly due to the nature of the tasks that he used and to the crude methodology, he was not able to find evidence for its existence and instead concluded that memories are diffused across the cortex and thus could not be localized.

In fact, with the advent of electrophysiology and the availability of chemical compounds, it was possible to demonstrate that indeed something changes when learning takes place and that there is indeed a physical trace or engram involving the synthesis of new proteins and the anatomical change in the morphology of the neurons involved. Thus, despite the type of memory or brain region involved, there is a uniform way in which learning becomes possible and that is found in the underlying biology (see review Bailey et al. 1996; Nader et al. 2000). Emotional memories are treated differently by our brain as emotion may signify information of great importance for our survival, a possible threat or danger. Thus, a creature able to remember such information well, may be better able to take the necessary measures to keep safe or avoid risk. Emotional memories are better remembered compared to neutral memories and are more resistant to decay due to the role of the amygdala, a structure just anterior to the hippocampus (Squire 2004).

However, the fact that memories are stored for a very long time does not necessarily mean that the memories themselves cannot be lost or that they are kept unchanged for ever, as the process of consolidation may imply. The most widely accepted ideas regarding forgetting seem to merge on the idea of interference, where learning that took place before or after acquisition of the new information interferes with the current

process of learning and memory. This idea has been challenged and rejected based on evidence which instead argues for a type of LTM which is more susceptible to change than previously thought. It is becoming apparent that memories are vulnerable once retrieved and they can be edited and re-edited upon each retrieval, and upon reconsolidation, a different version of the original memory may be stored (Dudai and Eisenberg 2004; Bonin and Koninck 2015). Thus, memories are potentially susceptible to distortion once retrieved (Nader et al. 2000). Research on those types of memories, which are particularly vivid and intense termed “flashbulb” memories, has also shown that there is distortion of memories no matter how intense they are, which can have implications in situations such as eyewitness testimonies, vulnerability towards suggestion, and false memories (see review: Hirst and Phelps 2016).

However, there may be even more active processes that not only hinder memories from remaining pure and intact but may promote the on-purpose removal of memories from the brain. New discoveries in *drosophila* suggest that there may be natural processes which induce active forgetting and that these may be working in order to promote an efficient memory system, which avoids overload and redundancy in the information it stores (Davis and Zhong 2017). These processes are taking place during sleep which seems to be the main platform for the maintenance and update of this complex and multi-process system called LTM memory.

Conclusion

It may well be that research on the acquisition as well as the forgetting aspects of memory will enhance our overall understanding of the nature of LTM as well as the particular phenomena which are closely related to memory. In light of new discoveries regarding the molecular players and the mechanisms involved in memory formation and maintenance, we are beginning to understand this ever-complex construct, which

although we are all familiar with, has remained quite elusive. Thus, although our knowledge regarding LTM has progressed enormously in the last few years, it seems that we are only half way in understanding the complete picture of this construct which is so integral to our daily functioning and survival.

Long-Term Partnership

- [Marriage](#)

Long-Term Potentiation

Androulla Ioannou and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Definition

Long-term potentiation refers to the persistent increase in synaptic strength following high-frequency stimulation of a chemical synapse.

Introduction

Long-term potentiation of synaptic transmission is a major mechanism for investigating learning and memory in the synaptic level. It is found in several regions of the brain, with the most prominent being the hippocampus thus its obvious involvement in the neural basis of some forms of memory Cooke & Bliss (2006).

Properties of Long-Term Potentiation

High frequency stimulation causes an increase in the efficiency of synaptic transmission, therefore enhancing the efficiency of the signal. For the induction of long-term potentiation, the activation of excitatory receptors is required Cooke & Bliss (2006). Bliss and Collingridge (1993) reported on the properties of long-term potentiation that differentiates it from other forms of synaptic plasticity: *input specificity* (it does not spread to other synapses), *associativity* (when a weak input of a single pathway is insufficient for the induction of long-term potentiation, simultaneous strong stimulation of another pathway can potentiate the weak stimulation), and *cooperativity* (apart from strong stimulation, long-term potentiation can be induced by the cooperation of many yet weaker stimulations). Since long-term potentiation occurs when a neuron shows an increased excitability over time due to a repeated behavior, and the heightened

synaptic transmission leads to the amplification of responses (i.e., pain), its involvement with the process of sensitization is high.

While the long-term potentiation of synapses in localized cell tissues seems to provide an elegant substrate for learning and memory, researchers turn their attention into experiments with the whole living organism (in vivo experiments). Morris et al. (1986) provided for the first time some data from in vivo experiments in which it was indicated that long-term potentiation was essential for the construction of memories. Using rats, Morris and colleagues were able to examine their spatial memory by inserting an *N*-methyl-D-aspartate (NMDA) blocker drug in their hippocampus, a brain structure implicated in learning. NMDA is a glutamate receptor and an ion channel protein within nerve cells, and it is responsible for the control of synaptic plasticity and memory function. Initially rats were trained to swim in a water maze, in order to find the platform hidden beneath (in the center and the sides of the pool) and escape. As soon as the rats were able to locate the platform, they were separated in two groups. One group constituted the control group while rats of the second group received the drug that blocks NMDA. Then both groups of rats were exposed to the water maze spatial memory task with the rats of the control group being successful in locating the platform and escaping the pool. Contrary, the second group of rats exhibited impaired performance, as long-term potentiation could not be induced indicating thus damage in the hippocampus. This series of experiments indicated that long-term potentiation is implicated in learning and memory processes.

Finally, dysfunctions in the process of long-term potentiation are thought to be implicated in mood disorders Post (2007) and neurodegenerative diseases as Parkinson's Cooke & Bliss (2006).

Conclusion

Long-term potentiation is a fundamental process in a cellular level with implications in the process of learning.

Loop Variant, The

Giovanni Randazzo
Department of Psychology, Oakland University,
Rochester, MI, USA

Synonyms

[Sidetrack](#); [Single person](#)

Definition

The Loop Variant is a variation of the moral dilemma problem called “the Trolley Problem” where a trolley can be redirected onto a different track with varying consequences and with the known benefit of saving a number of people.

Introduction

The Trolley Problem is a moral dilemma used first by philosophers starting in 1967 and then adopted by psychologists to examine moral thinking in humans (Cathcart 2013). The original problem was made by Philippa Foot in a philosophical paper about abortion. The original problem was simply many variations of a scenario where someone had to make a choice of killing one to save five, one of which was switching a tram to a different track (1967). The Loop variant is generally stated as such:

You are standing near a trolley track, there is a trolley heading down the track toward five workers who are unaware of the trolley and whom will die if nothing is done. There is a lever next to you, pulling the lever will redirect the trolley onto a separate track where one person is standing; redirecting the trolley will cause the one person to die. Do you stop the trolley by redirecting the trolley or let the trolley hit the five workers on the track (Greene 2013)?

The moral dilemma has many variations, including the track reconnecting the original track further from the four or five persons, the separate track having alarms, or the person on the separate track being of different descriptions (e.g., young or old; Bleske-Rechek et al. 2010; Greene 2013).

The Loop Variant

From an evolutionary perspective, the Loop variant is good for analysis of moral and spatial reasoning. For example, participants of the Loop Variant of the Trolley Problem are much more likely to sacrifice the individual when compared

to participants asked the Fat Man variation, which involves physically pushing a fat man onto the tracks (Greene 2013), showing that the difference in action and space has a significant impact on our moral reasoning.

Joshua Greene, April Bleske-Rechek, and Peter Singer are examples of psychologists and philosophers whom have used an evolutionary perspective in their analysis of the dilemma regarding the Fat Man variation. In Joshua Greene's *Moral Tribes* (2013), Greene takes an in-depth evolutionary approach to the Trolley Problem and the problems of many variations, including the Loop Variant. Greene found that only twenty percent of people were willing to push a man onto the tracks to save the five workmen (i.e., the Fat Man variation). However, over eighty percent of people were willing to switch the trolley onto the second track with one person. Pushing the man saves the most lives, but people have a negative emotional reaction to this choice. When instead given the option to switch tracks, this negative emotional response is weakened despite the end result of killing one to save five being the same (Greene 2013). Similarly, Bleske-Rechek et al. (2010) investigated the Trolley Problem using different descriptions of the man on the looped track. They tested this by replacing the man in the Loop Variant with relatives of varying genetic relatedness (0 to .5), people of varying age (2–70), or potential or current mates. They found that younger, more closely related individuals, and those who were current mates or likely to become potential mates, were less likely to be sacrificed for the five (Bleske-Rechek et al. 2010).

Both Greene (2013) and Singer (2005) argue that the reason for the variance in negative emotional reactions when sacrificing the single person is based on innate moral responses or empathy, which is further affected by our spatial reasoning. Pushing the man onto the track is a personally direct action, whereas pulling a lever is an indirect and distant action. This empathy response makes pushing the man difficult, but pulling the lever an easier choice since the five and one share distance, enabling a more objective response.

Conclusion

The Loop variant of the Trolley Problem is used to understand moral thinking in humans. The Loop Variant itself is the general situation where the trolley is redirected and someone is killed at some variable distance instead of having to push or drop a person that is nearby. Similar to variations in the Fat Man variation of the Trolley Problem (e.g., Greene 2013), the emotional response to killing the single individual to save the group of five is stronger when the single individual is younger or more closely related to the participant or is a potential mate (e.g., Bleske-Rechek et al. 2010), suggesting that moral reasoning varies according to context and the traits of the potential victim.

Low Birthweight and Preterm Infants

Daphne Blunt Bugental
Psychological and Brain Sciences, University of
California, Santa Barbara, CA, USA

Synonyms

Premature infants; Small infants

Definition

Infants who are smaller or have a lower gestational period than is normative.

Introduction

Low birthweight and preterm status of infants is an international source of concern, as is reflected in the priority placed on this issue by UNICEF and the World Health Organization. Although the death rates of such children are much higher in undeveloped countries, they also are a source of concern for many national agencies in the USA (e.g., US Department of Health and Human Services, Centers for Disease Control and Prevention). By their shared definition, infants born before 37 months of gestation or who weigh less than 5.5 lb are at risk for early health problems and a variety of long-term health, behavioral, and learning problems.

Doster et al. (2008) provided specific examples of the long-term outcomes of a large sample ($N = 903,402$) of low birthweight and preterm infants in Norway. They found that surviving children were more likely than other children to manifest cerebral palsy and mental retardation and/or receive public support as a disabled person.

In addition, low birthweight and preterm children create a major economic cost. The Institute of Medicine within the National Academy of Science (as summarized by McCormick, Litt, Smith and Zupancic in the 2011 *Annual Review of Public Health*) reported that the cost of prematurity (which strongly overlaps low birthweight) poses an annual cost (in 2005 dollars) of \$26 billion dollars – which includes costs of medical care, special education, early intervention, maternal health-care costs, and reduced work productivity for those involved.

Interaction Between Mothers and Low Birthweight or Preterm Infants

Preterm infants are exceptionally reactive to the emotions shown by their mothers. For example, they have been observed to demonstrate elevated levels of cortisol (an indicator of stress) when their mothers were depressed. In addition, they show low levels of responsiveness to their mothers' attention bids (Bugental et al. 2008). Thus, children's later development may be influenced by their early exposure to maternal depression. Field (2011) concluded, based on an extensive review of the literature, that children of depressed mothers are more likely to show a difficult temperament and a variety of behavioral, attentional, and emotional problems as well as illness at later ages.

Hagen (1999) argued that mothers who were depressed in our evolutionary past had help readily available from other women present in small groups. A mother who experienced depression, due to her loss of energy and reduced ability to provide care for her child, posed a threat to the larger group in that she is not contributing to their shared welfare. Her state of depression acted as a signal that others needed to provide assistance to her – thus renewing her involvement in community life.

In contemporary times, depressed mothers are more likely to lack access to social support, and thus they and their infants will have more adverse outcomes. This may be one of the advantages when obstetric units in hospitals provide birthing classes to expectant parents – an experience that also provides shared support between participants. As an

example, Feinberg and colleagues (2016) tested the long-term benefits of Family Foundations (a prenatal transition to parenthood program). Indicating a long-term outcome, they found that the program led to a reduced effect of depression and financial stress on infant birthweight, even after controlling for preterm status.

Shared care of infants by females living in small groups has a long history in evolutionary psychology. Hrdy is known for her work on “cooperative breeding” (Carter et al. 2006). According to this model, children were able to survive in the Pleistocene period because other group members (typically female) shared the care of the young (“alloparenting”). This allowed mothers of “costly” children (e.g., small for age or preterm) to continue producing more offspring.

Effects of Remediation

Given the effects of mothers on their premature/low birthweight children, researchers have shown interest in introducing interventions early in life. For example, interventions designed to reduce postpartum, maternal depression can also be expected to produce benefits for preterm children. As an early example, Brooks-Gunn et al. (1993) designed a 3-year intervention for low birthweight, preterm infants. The children in the intervention produced fewer behavior problems than those in the follow-up at age 3. In addition, Collins et al. (1993) not only found that women with high social support showed less postpartum depression, they also found that women with larger social networks had babies with higher birthweight.

Conclusions

Across countries, low birthweight and/or preterm children pose a “cost” to their caregivers (and potentially the community) if they lack an adequate support system. If these events are followed with maternal postpartum depression, infants will react to their mother’s emotional responses with stress. However, across our evolutionary history, mothers have been assisted by other kinfolk. In the present time, support classes are regularly

offered by medical facilities or social services – thus compensating for the absence of relatives who can provide assistance.

Lowering Partner Standards in a Short-Term Mating Context

Andrew G. Thomas
Swansea University, Swansea, UK

Synonyms

[Casual mating](#); [Mating preferences](#); [Partner characteristics](#); [Uncommitted mating](#)

Definition

Humans are more selective when considering partners for a long-term relationship compared to a short-term one.

Introduction

The characteristics modern men and women desire in a partner differ as a function of mating context. Overall, this pattern reflects a general

“relaxing” of standards in a short-term mating context compared to a long-term one. For example, compared to a long-term partner, both sexes are willing to tolerate a prospective casual mate who is lower in intelligence, kindness, and social status (Kenrick et al. 1993; Li and Kenrick 2006).

However, not all standards are relaxed in the context of casual mating. Desire for physical attractiveness in a potential partner, for instance, appears to be maintained, or even enhanced, in a short-term mating context compared to a long-term one (Kenrick et al. 1993; Li and Kenrick 2006). Understanding why standards are lower in some cases but not others requires both an appreciation of the challenges our ancestors faced when pursuing these two types of mating and how such challenges differed between the sexes.

Mating Strategies

As a species, humans mate within committed pair-bonds and uncommitted casual relationships (Buss and Schmitt 1993). Both types of mating conveyed a reproductive advantage to our ancestors under the right conditions, and each would have presented its own unique set of adaptive problems. As such, we evolved psychological adaptations to help us overcome these problems and draw us, given our circumstances, towards the most reproductively efficient type of mating (Thomas and Stewart-Williams 2018). It is the difference between these two sets of adaptations, or mating strategies, which cause potential long- and short-term partners to be held to different standards.

Global Standards for Long-Term Partners

Humans are a species which engage in mutual mate choice (Stewart-Williams and Thomas 2013). When looking for a long-term partner, both sexes hold high standards across a host of characteristics including physical attractiveness, kindness, and

social status (Kenrick et al. 1993; Li et al. 2002). These modern day preferences exist because human ancestors evolved to be highly selective when pair-bonding to maximize their reproductive success. Ancestral humans who chose long-term mates indiscriminately risked heavily investing in a small number of poor quality offspring, potentially without (or with ineffective) parental support from their partners. Such outcome would have handicapped the reproductive fitness of both sexes. There are, of course, some differences between the sexes in how much they value individual traits within a long-term context. However, it is rare to find traits highly valued by only one sex (Buss 1989; Kenrick et al. 1993).

Men's Standards for Short-Term Partners

Under certain conditions, ancestral humans could have maximized their reproductive fitness by foregoing pair-bonded mating and pursuing casual mating instead. This type of mating presents a unique set of adaptive problems which differ for each sex (Buss and Schmitt 1993). For ancestral men, casual mating offered the prospect of increased offspring quantity, with little to no investment. However, the success of this strategy would have depended on the availability of women willing to be uncommitted sex partners. Men with high standards for short-term partners would have limited this availability, especially given that highly attractive women may have been less likely to benefit from, and therefore pursue, short-term mating (Buss and Shackelford 2008). Thus, men evolved to have substantially relaxed standards for casual sex partners.

These evolved tendencies are visible in the preferences of modern men who, in the context of short-term mating, have lower standards across a broad array of characteristics including intelligence, conscientiousness, dominance, status, sexual history, and kindness (Buss and Schmitt 1993; Kenrick et al. 1993; Li and Kenrick 2006). One noticeable exception to this is the preference for physical attractiveness, which appears to be generally stronger in short-term contexts - likely due

to its association with both fitness and fecundity (Li and Kenrick 2006; Singh and Young 1995). It is worth noting that men are not indiscriminate in their choice of casual partners. This is probably due to the historical risks associated with short-term mating, including harmed reputation, STI contraction, and being manipulated by lower quality women into committed relationships (Greiling and Buss 2000). However, these risks likely constituted a smaller threat to fitness than those faced by women.

Women's Standards for Short-Term Partners

For ancestral women, casual mating could have enhanced fitness in several ways, mostly as the result of access to men of a higher mate value (Greiling and Buss 2000). These men, while reluctant to pair-bond with women of lower mate value, may have been willing to have casual sex with them to potentially increase their fitness with little to no investment. Thus, casual sex would have provided women with a way of securing the genes and resources of these men and may have given them an opportunity to coerce them into a pair-bond. Other benefits of short-term mating, such as manipulating a current partner, or practicing mate acquisition skills, may have been less related to the mate value of a prospective partner. Considering the benefits of short-term mating together, there would have been much less selective pressure on ancestral women to lower their minimum standards for short-term partners. Compared to men, women evolved to maintain higher standards for short-term partners, especially for characteristics that indicate high genetic quality.

Indeed, modern women relax their standards to a much lesser extent than men do. The attributes subject to the largest drop tend to be important for secure pair-bonding, such as family orientation and kindness (Li and Kenrick 2006). The desire for a physically attractive partner, however, tends to be either maintained or increased (Kenrick et al. 1993; Li and Kenrick 2006). Another reason why women evolved to be more discriminate about

short-term partners is that choosing poor quality partners as casual mates has greater fitness consequences for women than men. Obligate levels of parental investment are small among male mammals, who are able to desert a partner after pregnancy. In contrast, immediate desertion is not an option for females who have to carry an infant to term (Stewart-Williams and Thomas 2013). Choosing a poor quality short-term partner would have seen the reproductive resources of ancestral women directed towards poor quality offspring.

Conclusion

In summary, while humans are highly selective about their long-term partners, they appear to have lower standards for casual partners. The intensity of this “mating context effect” differs between the sexes, with men having markedly relaxed standards compared to women. This sex difference likely stems from the different costs and benefits casual mating afforded ancestral humans.

Luring Hypothesis

Claudia Chloe Brumbaugh and Alison Baren

Synonyms

Female mating strategies; Remating

Definition

A theory that single mothers use their daughters to attract new mates.

Introduction

Most people enter into marriage with the expectation that they've found a life-long mate. However, serial monogamy has been a consistent feature of mating behavior over human history. Today, people regularly find themselves single again well after young adulthood. About half of first marriages end in divorce, and many widowers have years ahead of them following the death of their spouse. Thus, people are frequently in a position to seek out new romantic relationships at later ages after having had children with past partners. Single mothers who have daughters may have a unique advantage when it comes to remating. Specifically, the "luring" hypothesis proposes a strategy in which mothers use pubescent daughters as *lures* to attract new romantic partners (Weekes-Shackelford et al. 2005).

Remating When There Are Existing Children

Between-sex conflict is common (e.g., Buss 1989), and such disagreements can occur over remating when prior offspring are involved. Because women typically get custody of children when a relationship dissolves, women are more likely to seek new mates while encumbered with children from past relationships. In human and nonhuman species alike, one male strategy to deal with a new mate's prior offspring is infanticide. For instance, children are 100 times more likely to be murdered or harmed by stepfathers than they are by their biological fathers (Daly and Wilson 2005). This behavior is advantageous to males, as eliminating previous offspring saves men from having to invest effort into unrelated children. Like males who have strategies to address remating when offspring are involved, females with children may have their own set of opposing adaptations to finding a new partner. Via the tactic of advertising children (specifically daughters), women may successfully attract men, while also countering male tendencies to disregard or dispose of unrelated offspring.

The Single Mother's Advantage

It is well known that men universally place great importance on physical appearance and youth in mates. In fact, men's preference for female attractiveness typically outshines their desire for most other favorable characteristics (Brumbaugh et al. 2014). Consequently, women are aware that men desire physical attractiveness and aim to meet those standards (Buss et al. 2000). Such awareness may have selected for a female psychology that exploits male mating preferences, not only in terms of how a woman behaves and looks (e.g., acting playfully and wearing makeup to appear youthful) but also in terms of how she uses female offspring to her benefit.

Women who are on the mating market and have daughters may find themselves at a unique

advantage over others (e.g., women with sons) in attracting mates. In other words, women who are old enough to have children and have lost some of their own youthful vigor may play into men's desire for physical beauty and youth via their daughters. Women's strategies may also work in concert with the shifting desires of aging men, who increasingly prefer relatively younger females as they get older (Conway et al. 2015). This male preference, paired with female reproductive value being highest immediately before a girl reaches menarche (Sugiyama 2001), may make adolescent daughters especially useful to mothers who are interested in attracting a new partner.

Preliminary Support for the "Luring" Hypothesis

The luring hypothesis is grounded in the idea that men's attraction to youth and beauty provides aging women with a way to secure new mates. Specifically, single women are predicted to benefit from their daughters, because the daughters serve to entice new romantic partners. Thus, mothers with daughters, compared to mothers with sons, should be more successful at acquiring new mates.

Some tentative support for the luring hypothesis exists. Examining the past 8 years of US Census data on living arrangements involving children under 18 years old who do not live with their biological father, 10.14 % of daughters lived with their mother and an unrelated cohabiting male partner, versus 9.89 % of sons who lived with their mother and a cohabiting male. This trend suggests that women may be more successful at obtaining a new mate when they have daughters rather than sons. Although promising, these data provide a broad snapshot. A closer examination of both mothers' and daughters' age could give greater insight into how luring operates. For instance, future work might examine whether luring is more frequent when women are older and nearing the end of their reproductive years, and the specific ages of daughters that make luring more successful.

Future Directions

One question that arises is the exact mechanism behind the luring hypothesis. In other words, is the process driven mainly by men gravitating to women with adolescent daughters or is it driven by women actively flaunting daughters to attract men? Men certainly seek out youthful partners, but there is also evidence of women's potential role in allowing their daughters to be sexual objects for their own new partners. For instance, research finds that mothers are less likely to believe their children's claims of sexual abuse by a stepfather compared to a biological father (Sirles and Franke 1989). Daughters of divorce may further contribute in implicitly helping their mothers lure new partners. For example, compared to girls living with both parents, girls living only with their mothers exhibit an earlier interest in sex (Draper and Harpending 1982). However, teenage girls also appear to display behaviors that may counteract their mother's use of them as lures. For example, compared to boys, girls have more difficulty adjusting to stepfathers (Hetherington et al. 1985). Thus, the role that daughters play in luring a potential male into a single-mother household remains unclear.

Conclusion

In conclusion, the luring hypothesis builds upon prior mate selection theories by postulating that women with daughters have an edge when it comes to remating. Evolutionarily advantageous strategies for obtaining mates are likely unconscious, including women's use of their daughters as lures and men's attraction to those daughters. However, numerous popular examples show that these mating behaviors are indeed in the public conscious. For example, males are portrayed as being sexually involved with their adult girlfriend's teenage daughters in the movies *Fish Tank* and *Mini's First Time*, and women are seen sexualizing their daughters on reality television programs such as *Toddlers and Tiaras* and *You're Grounded Forever*, but *First Let's go*

Shopping. The idea of adult men's attraction to teenage girls and women's use of their own daughters as lures seems unsavory, but the fact that we often see these things play out in pop culture suggests that these behaviors may be surprisingly normative.

Finding a new mate is especially critical for women with children, because it often helps to recover essential resources that were previously provided by one's past partner. However, the mating psychology of parents reentering the dating market has not been well studied. The luring hypothesis illustrates a novel and adaptive approach by which women may succeed in obtaining new partners.

Definition

Luteinizing hormone (LH) is secreted by the anterior pituitary and plays a role in reproductive functions such as ovulation in females and synthesis of androgens in males.

Introduction

The endocrine system plays an imperative role in the management of the human reproductive cycle. LH along with the two other gonadotropin hormones, follicle-stimulating hormone (FSH) and

human chorionic gonadotropin (hCG), are essential for the regulation of sexual and reproductive functioning. LH has an important evolutionary function as it acts on both male and female gonads (testes or ovaries). It plays key roles in biological processes such as sex steroid synthesis (for both sexes) and the critical reproductive mechanism of ovulation in females.

Biochemical Profile of LH

LH along with FSH are both stored in the anterior segment of the pituitary gland – pea-sized endocrine gland sitting at the base of the brain. Their secretion is stimulated by gonadotropin-releasing hormone (GnRH) secreted by the hypothalamus into the pituitary via the hypophyseal portal system (Martini et al. 2012). LH is a member of a heterodimeric glycoprotein family along with thyroid-stimulating hormone (TSH) and the other gonadotropin hormones (Choi and Smitz 2014). Members from this hormone family all share the same 92-amino acid α subunit, yet they each have their own respective hormone-specific β subunit that garners receptor specificity and subsequent functional specificity (Choi and Smitz 2014). In humans, the gene sequence encoding for the LH β subunit is located among a cluster of gene sequences on chromosome 19q13.32. Transcription of the LH β subunit is particularly important as it also happens to be the step in which production rates of LH are modulated (Choi and Smitz 2014). The structure of the highly conserved β subunit amino acid sequence is what provides LH with its essential biochemical behavior and function (Choi and Smitz 2014). Additionally, hCG has a 145 amino acid sequence coded from other genes among the aforementioned gene cluster but in the case of LH, this polypeptide is cleaved, thus shortening it to the complete 121 amino acid polypeptide used to form LH. This cleavage of the polypeptide ultimately results in a shorter circulating half-life for LH compared to hCG. This shorter half-life is key in generating the release of LH in the form of pulses that work in direct accordance with GnRH pulses (Choi and Smitz 2014; Martini et al. 2012). The release of LH in a

pulsatile fashion as opposed to a constant secretion is fundamental since GnRH pulses and corresponding LH pulses vary in frequency (amount released per minute) and amplitude (amount released per pulse), which ultimately drive cellular responses and the regulation of the reproductive cycle at its various stages, especially in females (Martini et al. 2012). LH exerts its action by binding the transmembrane LH/chorionic gonadotropin receptor (LHCGR) that is expressed in thecal cells, luteal cells, and differentiated granulosa cells of the ovaries as well as in interstitial cells of the testes, which is why LH is sometimes referred to as interstitial cell-stimulating hormone among males (Choi and Smitz 2014). This causes a conformational change in the receptor that activates a stimulatory G protein, which in turn activates enzymes such as adenylate cyclase and phospholipase C (Choi and Smitz 2014). Signal transduction pathways such as the phospholipase C/inositol phosphate pathway, the cyclic adenosine monophosphate/protein kinase A pathway, and the extracellular signal-regulated kinase 1/2 pathway result in proliferation and differentiation of the respective LHCGR expressing cells. These cellular developments consequently lead to maturation of the ovarian follicle and residing oocyte throughout the female menstrual cycle (Brown et al. 2010) as well as the regulation of sex steroid production in male testes.

LH Isoforms

Hormones such as LH exist within the human body as a conglomeration of isoforms (i.e., different forms of the same protein) that are created by natural gene sequence variation, metabolism of the hormone, or by posttranslational modification (Choi and Smitz 2014). Posttranslational modification has yielded in the upward range of 30 various LH isoforms and this is achieved mostly by the addition of carbohydrate side chains that are typically sialic and sulfonic acid compounds (Choi and Smitz 2014). These modify the hormones' biopotency (represented indirectly by bioactive-to-immunoreactive LH ratios [B/I]) and serum half-life. Sialylation extends longevity

of the hormone in blood serum while sulfonation shortens it (Choi and Smitz 2014).

Differences and variations between isoforms do exist between the sexes and within the female sexes' own reproductive cycle. During the luteal phase, B/I is low but begins to rise as the follicular phase progresses until it peaks at mid-cycle, which corresponds appropriately with the marked decrease in sulfonation and subsequent high concentration of circulating LH that is associated with ovulatory induction and the LH surge (Choi and Smitz 2014). Men, on the other hand, tend to have greater B/I and LH sialylation than premenopausal women but age progression is yet another factor that influences the LH parameters between the sexes (Choi and Smitz 2014). Women undergo an actual rise in LH B/I after menopause and an increase in LH sialylation and sulfonation, thus they carry a more acidic LH profile (Bergendahl and Veldhuis 2001). Men, on the other hand, actually experience a decrease or unchanged B/I as they age (Bergendahl and Veldhuis 2001). Furthermore, LH variants yielded from genetic sequence variations/mutations also have implications to both male and female reproductive function and success as these variants are frequently associated with fertility problems and dysfunctional LH properties. A common LH variant derived from a mutation in the β subunit gene sequence has been associated with female subfertility and menstrual irregularity (Bergendahl and Veldhuis 2001). In men, this same variant has been associated with the development of generally less favorable traits such as smaller testis, shorter stature, decreased serum insulin-like growth factor binding protein-3, and slowed linear growth rates (Bergendahl and Veldhuis 2001).

Basic Reproductive Function

Evolution hinges upon reproductive fitness – the capacity of an individual to successfully pass on their genes to offspring. LH plays a crucial role in this process by acting as a precursor to important sex hormones involved in this process. The fundamental purposes of LH for the reproductive functions of adult women and men differ with respect to the obvious distinctions between male

and female reproduction. In women, LH works to assist FSH in follicle stimulation and it also has the imperative role of stimulating ovulation and release of the ovum (Martini et al. 2012). This is accomplished by a large LH surge garnered by the positive feedback activity of rising estrogen on the pituitary, which triggers completion of meiosis I in the primary oocyte, rupture of the follicular wall, and subsequent ovulation 9 h proceeding peak LH levels (Martini et al. 2012). In the post-ovulatory phase, LH subsequently forms/maintains the corpus luteum by promoting progesterone secretion (Martini et al. 2012). The corpus luteum is a small yellowish hormone secreting structure that is formed from the remainder of the sac/follicle that once held the developing ovum. It functions in releasing large amounts of progesterone and small amounts of estrogen, which are critical to implantation and preparation for pregnancy (Martini et al. 2012). In men, LH is needed for androgenization during puberty, sexual differentiation, and sexual functioning. Male fertility is closely tied to adequate LH functioning since it is the precursor to testosterone, which in turn is crucial for sperm production, sperm motility, and energy acquisition by the way of augmenting sperm fructolysis and adenylyl cyclase activity (Ramanujam et al. 2000).

Indirect-Reproductive Adaptive Functions

LH appears to serve an important role in fertility-contingent shifts in women's reproductive physiology and psychology across the phases of the menstrual cycle. For instance, women in the peri-ovulatory phase (i.e., around ovulation) of the menstrual cycle when there is a surge in LH, experience changes in body odor (Miller and Maner 2010), adorn more promiscuous clothing (Durante et al. 2008), and are more flirtatious (Cantú et al. 2014). This research tends to be guided by the ovulatory shift hypothesis (Gangestad et al. 2005), from which it is argued that as the likelihood of conception increases toward ovulation pair-bonded women are predicted to be more attracted to men possessing characteristics putatively associated with good

genes (Gildersleeve et al. 2014). This effect is argued to be most pronounced when evaluating a man's desirability as a short-term partner and absent, or heavily attenuated, when assessing his desirability as a long-term mate. This is because women may only obtain genetic benefits from a mate when fertile. For example, men found women's body odors to be more attractive during the periovulatory phase (higher LH) relative to women in a low fertile phase (lower LH) of the menstrual cycle (e.g., luteal phase; Gildersleeve et al. 2012). During the periovulatory phase, relative to the luteal phase, women have also been shown to experience greater interpersonal closeness and satisfaction with their current relationships when pair-bonded to a sexually attractive mate (Larson et al. 2013).

To detect ovulation, researchers use different counting methods to approximate women's menstrual cycle phase position; however, investigators have tended not to verify these estimates using LH test strips to verify whether a surge in LH and ovulation have actually occurred or not (Jones et al. 2019). Recent tests of the ovulatory shifts hypothesis using larger samples, within-subject designs, and LH test strips are casting some doubt on the robustness of earlier evidence. Another challenge with this research is that fertility-contingent shifts in women's mating is influenced by several interrelated complex hormonal mechanisms and not just LH, such as estradiol, progesterone, and oxytocin (Jones et al. 2019).

The impact of LH on men's mating physiology and behavior is also somewhat unclear. Earlier researchers found that increases in men's LH corresponded to viewing sexually explicit material and heightened ratings of sexual arousal (LaFerla et al. 1978). Increases in men's luteinizing hormone-releasing hormone (LHRH) were also found in anticipation of viewing erotic stimuli (Evans and Distiller 1979). It is difficult to gauge the validity of these earlier studies because they are hampered by small sample sizes and low statistical power. In contrast, LHRH agonists (increasing the binding potential of LHRH) have been shown to lower sexual thoughts and behavior among male sexual offenders (Turner and Briken 2018). Elevated LH levels may also be a reliable biomarker of hypogonadism (impaired

sexual function) in older men (see Giannetta et al. 2012). These latter results suggest an inverse relation between heightened LH and decreased sexual arousal and mating effort. It is evident that more work is needed to examine the relations between men's LH levels and their reproductive physiology and psychology, which are complicated by the pulsatile release of this hormone.

Indirect Immune Function

Immune function has been linked to the reproductive hormones of males and females, with LH playing a contributory and noncausal role, as a precursor hormone. Estrogen acts as an immunoenhancing hormone by regulating B cell function, preventing selection of autoreactive B cells, and inducing a Th2 immune response, which includes various Interleukins (IL) that play an important role in immune/B cell function (Taneja 2018). Furthermore, estrogen stimulates T-lymphocyte homing via expression of the CCR5 gene (Taneja 2018). In contrast, testosterone, which is known widely for its immunosuppressive effects in human males and does so by evoking a Th1 immune response, reduces the action of natural killer cells and tumor necrosis factor-alpha (Taneja 2018). Testosterone also enhances the production of the anti-inflammatory IL-10, which inhibits many important immune cells (Taneja 2018). The obvious immunomodulating differences of the reproductive hormones imply an evolutionary link between LH and immune function, due to the principal actions of its downstream hormones.

Areas of Future Inquiry

Scientific evidence of LH's direct immune functions in humans is sparse and limited, but over the past decades animal researchers have suggested potential links between LH as a causal agent of immune function. For example, LH supplementation was found to promote fetal tolerance in abortion-prone female mice (Schumacher et al. 2014). It did so by increasing the number of regulatory T cells, and by reducing the effects of the

tolerogenic dendritic cells – antigen-presenting cells (Schumacher et al. 2014). Lastly, areas of future inquiry may prove beneficial by investigating the direct immunological effects of endogenous LH in humans.

Mail-Order Brides

Francis T. McAndrew
Knox College, Galesburg, IL, USA

Synonyms

[International brides](#); [Internet brides](#); [Picture brides](#)

Definition

Mail-order brides are women who are explicitly seeking marriage and advertise themselves with agencies that publicize their availability.

Introduction

The term “mail-order bride” originated on the American frontier in the nineteenth century. At

that time, the number of men on the frontier far outnumbered the number of available women, and lonely farmers and ranchers would seek wives from “Back East” by placing ads in newspapers and magazines. Interested women would write back and send photographs, and the couple did not usually meet in person until the woman showed up for her wedding.

The Modern Mail-Order Bride Industry

Twenty-first-century mail-order brides advertise themselves through international marriage agencies. These agencies have names such as *AnastasiaDate.com*, *Loveme.com*, *RussianBrides.com*, and *GlobalLadies.com*. What distinguishes mail-order brides from other mate-seeking women is that they are trying to expand their pool of eligible mates across national borders, and they do so in a way that preserves a freedom of choice that would be greatly diminished if they were to employ more traditional matchmakers. Most mail-order brides now come from Southeast Asia (especially Thailand and the Philippines), Latin America (often Colombia and Brazil), and Russia and the Ukraine. The prospective husbands they seek come primarily from the United States or Western Europe, although there is a market for foreign brides in South Korea and Japan as well (Johnson 2007; Ordoñez 1997). As Wilson (1998) has observed, the photographs of these women that are placed on an agency’s

website are in some sense “*passport photos for foreign eyes and a ticket out of Southeast Asia*” (p. 117) or wherever else from which they might hail.

Another factor that may influence a woman to seek a husband as a mail-order bride is family pressure, especially when she has already reached an age by which she is supposed to have been married. Kojima (2001) identified this pressure to escape the social stigma attached to single women in Korea as a primary motive for Korean women’s emigration to Japan in search of a husband.

Recent Research on Mail-Order Bride Mating Strategies

Although the motives of women seeking Western husbands are often driven by economic concerns, this is not always the case (Johnson 2007; Minervini and McAndrew 2006); mail-order brides are drawn from throughout the social spectra of their respective societies. In two studies, Minervini and McAndrew (2006) examined the mate preferences of mail-order brides from Colombia, Russia, and the Philippines. They conducted in-depth interviews with several “brides,” husbands of mail-order brides, and the proprietor of a mail-order bride agency in Colombia. These interviews revealed that a wide range of factors play a role in the mail-order bride mating strategy. When asked why American customers seek Latina women, the proprietor of the match-making service said that American men prefer Latina women as wives because they are believed to take better care of their husbands and are more tender, warm, and dedicated to their home than are American women. The matchmaker also reported that his American customers sought women who were younger than themselves and those who had stereotypically Latin features such as tan skin and long, dark hair. Latina women, he believed, are interested in American men because they are thought to be more faithful, less jealous, and less chauvinistic than Latino men. The interviews captured the irony of situations in which women who were attempting to escape from traditional constraints were being matched with men who were

attempting to find a wife whom they believed would embrace these very constraints.

For example, an American man who married a mail-order bride had this to say about family life:

The husband and wife are equal partners in the family structure, though not the same. Men and women are different in physical and mental abilities. I feel that the wife has her place in the family structure, such as giving more care to children, the house, and things of that nature. The husband should take care of income and things of that nature.

Similarly, another former husband (age 65) of a mail-order bride stated that he felt that American women:

were too interested in what I was worth [economically]. With women’s liberation in the USA, I had them calling me, coming to my house. Before, the man called the woman when he wanted to date her; the woman was not the initiator. Now is so different from what I grew up with, so I thought that the best thing to do was to meet someone that can’t just come to my house.

A woman now living in the United States explained her reasons for becoming a mail-order bride:

I met men in Colombia, I was married, I had my experience. I decided to look for something different, try men from another culture that might be better than ours. American men are more serious; [they] worry and respect their wife.

Thus, the mail-order bride business as it now operates may be in the perverse position of attempting to match independent, nontraditional women with very traditional Western men, a situation which frequently leads to dissatisfaction for both parties.

Minervini and McAndrew (2006) surveyed a group of Colombian women who were attempting to become mail-order brides, and they compared them with a group of Colombian women who were not pursuing a husband in this way. In addition to asking about their preferences for a husband, they also asked them what they thought men were looking for in a wife. The responses of the two groups to open-ended questions about mating were much more similar than different, and the items relevant to what they wanted in a prospective husband were the ones that showed the least

difference. Both groups emphasized the importance of sexual fidelity and commitment as traits to look for in a mate as well as traits to advertise about one's self. These results line up nicely with the responses to a third question in which the women shared what they thought men sought in a wife, as they believed that these were the two most important qualities that men were after. In a second study, Minervini and McAndrew also found a high degree of agreement among mail-order brides from Russia, Colombia, and the Philippines. Across the board, they found a preoccupation with the very same characteristics (e.g., ambition, commitment to a relationship and children, sexual fidelity, a mate that is somewhat older) that have been documented by evolutionary psychologists in a great many studies.

Mail-Order Brides and Domestic Violence

It must also be acknowledged that there is a very dark side to the mail-order bride experience. Women who travel to a far-off country to marry a stranger are putting themselves at great risk, and grim statistics confirm the danger. Many incidents of violence (including murder) against mail-order brides have been well documented, especially in the United States and South Korea (Crandall et al. 2005; Osipovich 2005). It is not unreasonable to assume that awkward or sinister men are overrepresented in the pool of males who choose to pursue mates from so far away, and women should proceed with great caution if they choose to explore mating opportunities in this fashion.

Conclusion

Women willing to become mail-order brides do not appear to have a different agenda than other mate-seeking women; they simply have discovered a novel way to expand their pool of prospective husbands. However, the mail-order bride mating strategy may be putting women at risk for sexual and physical violence, and it may not be the ideal way of connecting with men who value independence in a mate.

Making the Best of a Bad Job

Charlyn Partridge
Annis Water Resources Institute, Grand Valley
State University, Muskegon, MI, USA

Synonyms

[Alternative reproductive tactics](#); [Conditional strategies](#); [Mating tactics](#)

Definition

Individuals that are less favored may use alternative reproductive tactics that minimize their disadvantage (Dawkins 1980).

Introduction

The “making the best of a bad job” scenario was derived as a way of explaining how some reproductive tactics are maintained in a population even when those behaviors result in lower fitness compared to dominant/territorial tactics. For example, small individuals may not fair well in direct competitions with dominant males. Rather than competing, small males may find alternative means (i.e., sneak copulations) that downplay their disadvantage to gain some reproductive success. Accordingly, the “best of a bad job” tactic can have lower reproductive fitness than the dominant tactic.

Something Is Better than Nothing

One of the major questions in evolutionary biology is how phenotypic variation is maintained within a population. This is particularly true for discontinuous phenotypes such as alternative mating strategies. When one mating strategy appears more successful than another (i.e., has higher reproductive fitness), why does not selection remove the less successful strategy? One proposed mechanism is that these behavioral differences may not be alternative strategies but one conditional strategy. A conditional strategy involves a “choice/decision” in how to behave dependent upon the relative condition or status of an individual (Dawkins 1980; Maynard-Smith 1982) (see ► [Mating Strategy Equilibria](#)). Individuals of “status A” should perform “tactic X,” and individuals of “status B” should perform “tactic Y” (Dawkins 1980). However, it should be noted that the “choice” in tactic does not have to be conscious. For example, if only large individuals can hold and maintain breeding

territories, small individuals employing a territorial tactic would likely always lose. In this situation, small individuals should use alternative ways of gaining matings that minimize this disadvantage, thus “making the best of a bad job” (Dawkins 1980). It is not expected that these tactics be equally successful, but small males can achieve some reproductive success. In primates it is thought that most alternative reproductive tactics are “best of a bad job” phenotypes. For instance, mandrill (*Mandrillus sphinx*) males of low status may live alone, rather than in groups, and try to increase their reproductive success by visiting multiple groups during the breeding period to obtain opportunistic matings (Wickings et al. 1993). These tactics are not equal in their reproductive success, as alpha males always have higher reproductive success compared to solitary males (Wickings et al. 1993). However, the non-prime male will likely gain higher reproductive success by acting as a solitary transient male than by remaining in a group.

Not “Bad,” Just Efficient

Some alternative tactics are assumed to be “making the best of a bad job” when in fact, this may not be the case. It has often been suggested that “sneaker” tactics, where smaller individuals sneak copulations rather than directly compete with dominant males, are simply trying to minimize their size disadvantage. In both salmon (*Oncorhynchus* spp.) and sunfish (*Lepomis* spp.), the territorial and sneaker tactics often represent distinct life histories. Sneaker males (or jacks in salmon) mature earlier and invest in reproduction, while territorial males delay maturation and invest in growth. Once they reach adulthood, territorial males are much larger than sneakers. Territorial males also fertilize a higher proportion of a brood than sneaker males (Neff 2001; Berejikian et al. 2010). Therefore, at face value it would seem that males using a sneaking tactic are making up for their obvious size disadvantage. However, as juveniles, sneakers in both salmon and bluegill

have faster growth rates than territorial males (Gross 1984; Gross 1991a, b; Neff 2004), and bluegill sneakers have higher survival rates (Neff 2004; Neff and Lister 2007). These are traits more often associated with individuals in good condition rather than poor. That begs the question, are sneaker males really poor-quality males compensating for smaller size? For both salmon and sunfish sneakers, reproductive fitness is related to their frequency within the population (Gross 1984; Gross 1991a, b; Berejikian et al. 2010). When sneaker frequency is high, their reproductive fitness is low, but as they decrease in the population, their reproductive fitness increases (Gross 1991b; Berejikian et al. 2010). This frequency-dependent selection coupled with differences in age to maturity can maintain alternative tactics in an evolutionary stable state, with both tactics having equal lifetime reproductive fitness (Gross 1991b). In addition, some data suggest that bluegill sneakers may even have higher lifetime reproductive fitness than territorial males when differential survival is included (Neff and Lister 2007). Therefore, prior to determining whether a tactic is truly a “best of a bad job,” one must consider a number of additional factors, including frequency-dependent selection, age to maturity, and differential survivorship, before assessing whether the reproductive fitness of one tactic is actually greater than another tactic.

Conclusion

When an alternative reproductive strategy is conditional, low-quality individuals may employ a “best of a bad job” tactic as a way of minimizing their disadvantage. These tactics often have lower reproductive success than dominant tactics, but they do provide some mating opportunities for less favored individuals (Dawkins 1980). While many alternative tactics may appear to have lower reproductive success at first glance, differential survival, maturity rates, and frequency-dependent selection may lead to equal lifetime reproductive fitness.

[Adaptation failure](#)

Definition

Failure in the process of adaptation.

Introduction

The Merriam-Webster dictionary defines “maladaptation” as poor or inadequate adaptation (Dictionary 2006). Adaptation is highly essential for the survival of an organism. The process of adaptation makes an organism fit to meet the needs of the environment. The concept of adaptation and maladaptation is applicable to all living organisms. In the ecosystem, degree of adaptation and maladaptation varies across different species of organisms. Adaptation helps in survival and continuation of race, whereas maladaptation may result in extinction. Survival of many organisms depends upon presence or absence of several other organisms. For example, in the ecosystem, certain birds feed on insects. Extinction of birds will result in overgrowth of insects in terms of their number and vice versa. Similarly, in the aquatic ecosystem, fishes feed on algae. Abundance of algae facilitate abundance of the fish population. In this manner, maladaptation of one species may influence the expansion/growth (in terms of abundance) or extinction of other species (Farkas et al. 2015). However, this entry will focus more on the maladaptation processes in human beings and their health significance.

During the life course of human beings, series of physiological transitions (fetal to extrauterine

life, pubertal changes, pregnancy and lactation, menopause) happen. During the physiological transitions, adaptation process plays a role. Failure of adaptation during these phases may result in development of illness. For example, neonatal hypoglycemia may result from maladaptation to the extrauterine environment (Ichord and Bearden 2017). There are various causes of maladaptation. Broadly, certain biological (e.g., genetic), psychological (e.g., personality), and environmental (e.g., sociocultural) factors determine maladaptation. Evidences support that genetic factors – mutation, inbreeding, pleiotropy, etc. – attribute to maladaptation (Crespi 2000).

Types of Maladaptations

Maladaptation may occur in the structural (physical), functional (physiological), as well as behavioral level. Congenital malformations result in structural deformity and may result in maladaptation. For example, cleft lip and cleft palate may cause impairment of speech. Physiological maladaptation results from alteration of the intracellular or extracellular milieu. For example, poisoning alters the cellular physiology (carbon monoxide poisoning results in hypoxia). Similarly, organ failure (e.g., liver, kidney) results in failure in adapting with the physiological demands of the body. Sometimes the structural alteration may result in functional alteration. For example, congenital heart diseases result in alteration in cardiorespiratory physiology. Behavior of an individual facilitates adaptation. Behaviors are often directed to meet the basic needs of life (seeking food, shelter, sex). Maladaptive behavior interrupts the normal integrity of life. For example, addiction as a maladaptive behavior results in impairment of physical and mental health as well as impairs social integrity.

Health Significance of Maladaptation

During the course of meeting the changing needs of environment, at times there may be failure of

adaptation. Maladaptations (failure of adaptations) may result in development of various health hazards (e.g., abnormal neuroplasticity resulting from maladaptation may result in phantom limb pain syndrome, tinnitus) (Nava and Röder 2011). Chronic pain is a form of maladaptation which often results from damage at any part in the course of pain pathway (Hyam and Zrinzo 2018).

Adapting to the changing environment is highly essential for the general well-being. Travellers, travelling long distances in flights across time zones, may develop “jet lag” due to maladaptation, which results from mismatch of the body’s circadian clock with the new time zone (Waterhouse et al. 2007). Mountain sickness (high-altitude sickness) results from acute exposure to high altitude. The individual experiences hypoxia due to reduced oxygen partial pressure at higher altitudes. Pulmonary edema may develop as a consequence (Mohsenin et al. 2017). Certain individuals experience “motion sickness” during travels. This results from maladaptation of the vestibular system and visual inputs with the movement (Golding and Gresty 2015). Individuals, who are not able to adapt with the provocative environmental stimuli (situations), are more likely to experience motion sickness. Successful adaptations diminish the severity of motion sickness.

Maladaptation can occur at the cellular level. Cells of different individuals respond differently to environmental stressors. Even in the same individual, different cells respond differently to a similar kind of environmental stressor. Maladaptation in the cellular responses may occur in bronchial asthma (Agrawal et al. 2009).

Allergy and hypersensitivity reactions often result, when the immune system of the body becomes unable to adapt with a sensitive agent (allergen) and becomes over-reactive to it by releasing various chemical mediators (Tanno et al. 2016).

Metabolic changes in the body can happen as an adaptive response as well as a maladaptive response. Adaptive metabolic changes help in maintaining the integrity, whereas maladaptation

results in disruption of the integrity. Organs in the body are putting continuous efforts to adapt with the environment. Many cardiac diseases (congestive heart failure, cardiomyopathy, hypertension) and metabolic disorders (diabetes mellitus, obesity) result from maladaptive physiological responses (Young et al. 2002). The myocardium has the ability to compensate the environmental stress. Failure of the myocardium to sustain stress leads to decompensation, which is often the resultant of maladaptation process. During this process, excess release of immune mediators (cytokines like tumor necrosis factor, interleukins) occurs, which produces cardiac decompensation (Mann 2003). Similarly, maladaptation plays a role in the pathogenesis of chronic kidney diseases (Ketteler et al. 2013).

Grief is a common phenomenon experienced in life by most of the individuals after losing their close ones. Over a period of time, people able to cope with the loss and recover from the pains of grief. However, it may persist in certain individuals for longer time producing significant distress, which is commonly referred to as pathological grief and is a result of maladaptation (Jacobs 1993). Similarly, anxiety disorders, depression, and stress-related disorders may result from maladaptation. Individual vulnerability plays a pivotal role in development of these disorders. The individuals vulnerable for these disorders often not able to adapt with the environmental needs and hence might be manifesting the disorders (Jacobs 1993). Recent evidences support that exposure to multiple traumatic events result in maladaptation, which might attribute to development of dissociative symptoms (Granieri et al. 2018). Maladaptive personality plays a determining role in development of trauma-related dissociation.

Psychosocial Relevance of Maladaptation

School plays an important role in an individual's life. The environment of school is more structured

than the home environment, and children often face challenges to adapt to the school environment. Adaptation to the school environment is often considered as a key predictive factor of academic excellence (Bravender 2009). Maladaptation to school may result in declined scholastic performance, school refusal, dropout, and truancy (Bravender 2009). Evidence supports the role of maladaptation and adaptation (adjustment) in ego development. Individuals, who successfully adapt, are less likely to experience psychological distress than those who had maladaptations (Noam et al. 1991). Recent evidence revealed that maladaptations in early life (failure of self-regulation in preadolescent period and negative social interactions during adolescence) may lead to development of psychological disturbances in later life (Laceulle et al. 2019).

Evolutionary Significance of Maladaptation

The environment keeps on changing, and the change creates a demand to bring changes in all the living beings within the ecosystem. Every living organism tries to evolve to cope with the changing environment. Those organisms, who effectively cope or adapt with the change by modifying their structure and function, survive harmoniously within the nature, and those who fail to meet the same struggle to survive. Organisms failing to adapt often become extinct.

Evidences suggest that there is continuous change in human brain to meet the changing needs of the environment. During this process there is structural as well as functional changes in the brain, which is commonly referred to as neuroplasticity (Nava and Röder 2011). Natural selection is an important process in evolution. Maladaptation has been linked to natural selection. Maladaptation results from suboptimal designs (programs). George Williams proposed several evolutionary explanations (e.g., mismatch, coevolution, constraints) for the sub-optimal designs that attribute to maladaptation (Nesse 2005).

Conclusion

Maladaptation is an important alert sign. There is a need to identify and understand maladaptation, in order to prevent its occurrence and persistence. Correcting maladaptation, early, may minimize the distress and impairment significantly.

Ecological trap; Evolutionary mismatch; Evolutionary trap; Mismatch theory; Maladaptation

Definition

In evolutionary psychology, maladaptive theory holds that some human behaviors are the result of past selective forces that are no longer operative, usually because of changes in the physical and social environment, resulting in behaviors that are no longer beneficial for fitness.

A maladaptation is a feature of an organism that, despite being genetically encoded or influenced, hinders the biological fitness of the individuals that bear it. Rarely is it straightforward to determine that a given trait is unambiguously maladaptive. Indeed, as noted by Crespi (2000), “Conditions for unambiguously identifying maladaptation are considerably more stringent than those for demonstrating adaptation.” Nevertheless, the existence of maladaptive physical and behavioral traits is undeniable and reminds us of the limits of adaptationist explanations for human behaviors.

At its very origin [pardon the pun], modern evolutionary theory has acknowledged the limits of natural selection in explaining every single feature of an organism. Darwin’s insight that, “many structures now have no direct relation to the habits of life” remains a valid, if oft-forgotten qualifier (Darwin 1859). Despite the emergence of the neutral theory of variation (Kimura 1983) and the identification of so-called evolutionary

“spandrels” (Gould and Lewontin 1979), the ghosts of adaptationism persist, particularly in popular science writings, and more specifically in the just-so stories that dominate popular evolutionary psychology. While the tendency to pin every quirk of modern human behavior on adaptation to Pleistocene Africa makes for sciency entertainment, serious theoretical work in evolutionary psychology requires a higher standard.

By definition, a maladaptation reduces reproductive success in some way and therefore calls out for an explanation as to its emergence and/or persistence in a population. This explains both the interest in and controversy of the topic. Perhaps the most frequent explanation for maladaptation is something now called *mismatch* (Gluckman and Hanson 2004). A mismatch trait is one that was adaptive in the ancestral milieu, but is maladaptive in the present, most often due to a change in the environment. A commonly cited human behavioral example is our appetite for sweet foods. For millions of years prior to the dawn of agriculture, human ancestors encountered few foods that were high in mono- and disaccharides, the natural dietary ligands most often responsible for the perception of sweet (Eaton 2006). Those few were mostly fruits, so it is thus inferred that the human sweet tooth was at least partly an adaptation driving us to seek the specific foods that provide an essential nutrient found in many fruits: vitamin C (Breslin 2013). However, beginning with the cultivation and subsequent artificial selection of carbohydrate-rich cereal crops, along with the selection of larger and sweeter fruits, the production of honey, maple syrup, cane sugar, and so on, humans have tremendously increased dietary intake of simple sugars which have been almost completely decoupled from vitamin C (Eaton 2006). Given the mounting evidence that excessive consumption of simple sugars correlates with a variety of poor health outcomes, the human appetite for sugar may fairly be called maladaptive under present conditions (Jew et al. 2009).

Mismatch, an environmental change that has yet to be addressed adaptively by an organism, is but one possible cause of maladaptation. Others include genetic drift, the fixing of a maladaptive

trait by chance; heterozygote advantage, the persistence of a harmful allele, even when a non-harmful alternative exists in the gene pool, due to the advantage that hybrids have over either form of homozygote; genetic linkage, the connectedness of a maladaptive trait with an adaptive one through either pleiotropy or close chromosomal association; and gene flow, the mixture of alleles and traits from two populations that have adapted to different environments. In these cases, with the possible exception of heterozygote advantage, continued selection could presumably correct the maladaptation, though unambiguous examples of this are lacking.

General theories of maladaptation have remained elusive in part because the very concept is strictly context-dependent. This is best illustrated by example. Humans have substantially less hair and substantially more sweat glands than chimpanzees per unit area (Rogers et al. 2004; Zihlman and Cohn 1988). The prevailing view is that both of these traits are adaptations to the much dryer air of the grasslands, compared to that of the rainforest, the habitats of our more proximal and distant ancestors, respectively. Central to this hypothesis is the notion that Pleistocene hominins were persistence hunters, an activity in which the advantage of both hairlessness and copious sweating has been demonstrated (Bramble and Lieberman 2004). However, as archaic humans and other hominins migrated northward, the dearth of body hair represented a distinct *disadvantage* in the colder, wetter climates that greeted them. Hairlessness, then, can convey an advantage or disadvantage based on context. (It is worth noting that adaptationist interpretations of modern hair distribution are not without challenges. See Morris 1994.)

As difficult as it is to apply adaptive and maladaptive interpretations to matters of anatomy and physiology, it is incredibly more so with complex behaviors. The current teleology of a behavior is difficult enough to assess on its own, especially cross-culturally, and the phylogenetic analysis is even more so. Indeed, the substantial behavioral discontinuity between humans and their extant relatives dooms many phylogenetic analyses within human evolutionary psychology. Notwithstanding

that caveat, behavior, particularly reproductive behavior, may be the richest area of maladaptation given how directly sexual selection can act on reproductive success, particularly in highly social animals with marked intrasexual competition, e.g., humans and our close relatives. For example, frequency-dependent sexual selection, the advantage enjoyed by uncommon mating strategies, is inherently fickle. Insofar as they are genetically based, a sexually selected mating strategy can switch from an adaptation to a maladaptation in as little as a single generation (Lande 1980; Pomiankowski 1987).

Suicide as an Adaptive or Maladaptive Behavior

Recently, suicide has come under scrutiny as a possible maladaptive behavior. Tragically, suicide has long been a significant cause of death among humans, especially males. In 2016, 45,000 people died by suicide in the United States, more than double the number of homicides, making this the second leading cause of death of those age 10–34 and fourth most common cause of death among those aged 35–54 (CDC 2017). To call this a conundrum for an adaptationist view of evolutionary psychology would be an understatement, especially given that the peak age of suicide attempts correlates closely with the peak reproductive years in both males and females.

The notion that suicide may provide adaptive benefits in some contexts is controversial but has both theoretical and experimental support (Gyllenberg and Parvinen 2001; McAndrew 2002). In theory, if self-removal from the gene pool results in a net increase in the fitness of close relatives that is greater than the loss of personal fitness, the principle of inclusive fitness holds that suicide could emerge as an adaptive behavior. In this model, kin-selective altruistic suicide could be driven by self-interested genetic elements. In support of this theory, those who survive a suicide attempt very frequently report an overwhelming feeling of being burdensome to their families, which is even more common among those who are beyond prime reproductive

age or who suffer from major chronic illness, a known risk factor for suicide, and are of low reproductive potential more generally (though these are minority of total suicide attempts, successful or not) (Kovacs and Garrison 1985; Juurlink et al. 2004; Gould et al. 2003). Further supporting this notion is the otherwise paradoxical statistic that suicidality shows considerable heritability (Brent and Mann 2005; Voracek and Loibl 2007).

One example of adaptive suicide is found in traditional Inuit culture. During times of severe famine, elderly members of a family have been known to walk as far away from the camp as they can until they collapse from exhaustion or hypothermia where they are left to die (Leighton and Hughes 1955). Because this spares family resources for their children and grandchildren, and because they are beyond reproductive age themselves, the connection to inclusive fitness is direct.

The myriad differences between the modern world and the environment of evolutionary adaptedness could explain suicide as an adaptive-turned-maladaptive behavior. In other words, suicidality may be a mismatch disease due to modern population densities that are orders of magnitude higher than the ones our species experienced for millions of years prior to urbanization. Indeed, a connection between suicide rates and population density has been observed under certain conditions (Galle et al. 1972; Levy and Herzog 1974; Yamasaki et al. 2008). This is not to suggest, however, that suicide is a form of quorum sensing and population control. Indeed, that hypothesis would rest entirely on group selective theory, a shaky foundation.

There is at least one additional adaptationist theory of suicide that warrants mention although full exploration of which is outside of the scope of this entry. The *bargaining hypothesis* holds that suicide attempts are a form of honest costly signaling designed to help an individual in an otherwise untenable situation recalibrate various social relationships and cultural realities (McAndrew 2002; Henrich 2009). This falls under the “cry for help” paradigm of understanding suicidality and is buttressed by the fact that the overwhelming majority

of suicide attempts are both publicly observable and unsuccessful.

Sex differences in suicidality may be relevant to both of these theoretical frameworks because death by suicide is much more common among men, while among women, suicide attempts are more often unsuccessful (Oquendo et al. 2001). It is possible that gender differentially activates the two frameworks of suicide discussed here in ways related to other gender-influenced behaviors such as impulsivity, risk-taking, and sexually selective costly signaling.

Honor Killings as Maladaptive Behavior

While suicide is often considered the most direct affront to one’s personal biological fitness, the murder of one’s children is a close second. Nevertheless, so-called *honor killings* of children by their parents are a noted phenomenon in several different cultures. These murders are wrought upon young women far more often than upon young men and are most often conducted by the father, usually with the assent of the mother, and sometimes with the aid of his brothers and/or sons, the victim’s uncles and brothers. Shockingly, these murders are rarely concealed and may even be conducted in public. Regions in which this enigmatic behavior is observed with some regularity include the Middle East, North Africa, and the Indian subcontinent (Chesler 2010). While its occurrence in Muslim communities, especially those in the West, has attracted the most media attention, honor killings have also been observed in contemporary Hindu and Jewish contexts and the upper classes of Medieval and early modern Europe (Bowman 2007).

Recently, Robert Trivers has invoked kin selection and inclusive fitness theory to attempt to explain the phenomenon of honor killings (Trivers 2018a, b). Importantly, most of the modern cultures in which familial honor killings occur have a high degree of first-cousin marriage. In a society with strong borders and low gene flow, frequent first-cousin marriage markedly raises the degree of genetic relatedness between individuals and their second-degree relatives, e.g., nieces and

nephews. If identical twins show a genetic relatedness (r) of 1, while genealogical nonrelatives show an r of 0, in a society in which first-cousin marriage is rare, siblings have an r of 0.5, as do parents and children, and second-degree relatives have an r of 0.25. However, as rates of first-cousin marriage rise, the r among genealogical relatives increases gradually, can surpass 0.5 within a few generations, and continues rising asymptotically to 1. Within-family genetic diversity thus drops precipitously.

The exception that proves the rule is traditional Hindu culture. Although first-cousin marriage is not common among Hindus, marriage customs have adhered to the caste system since antiquity, which permits only endogamous marriage. This has the same long-term evolutionary genetic effect as frequent first-cousin marriage, raising the genetic relatedness and reducing the genetic diversity within castes.

Under a system of high genetic relatedness, if the murder of an offspring preserves the reproductive potential of the victim's siblings and cousins, it can boost the biological fitness of the murdering father or sibling, despite the total loss of the reproductive potential of the murdered individual. In all of the honor-based cultures listed above, shame carries substantial costs to reproductive potential and passes freely among first- and second-degree relatives, including first cousins. If a young person behaves in a way that brings shame upon her family, and that shame is broadly recognized in the community, the father of the shameful actor may indeed be acting in the interest of his own inclusive fitness when he murders his daughter. While the tight correlation between the two phenomena of honor killings and first-cousin marriage is compelling, a mechanistic explanation has yet to be suggested.

This behavior is very likely maladaptive in industrialized societies. Firstly, the social-reproductive costs of vicarious shame are rapidly attenuating around the world. Secondly, in the West and in developed regions of the East, the modern state imposes criminal penalties for murder with no official amelioration of punishment for honor-motivated killings. (There is some evidence that, the "culture defense" resulted in

lighter sentences for honor killings in the United Kingdom through the 1990s, but this does not appear to the case post-2001 (Gill 2009).) This punishment extends well beyond the adjudication of the murder, as the family of a convicted murderer will experience substantial negative consequences as well, which may very well be reflected in reduced biological fitness, although this has yet to be examined.

Adoption

Parental adoption involves the substantial investment of one's resources into non-kin children at the expense of, or even sometimes *instead of*, one's own genetic progeny. As such, adoption generally confers *negative* biological fitness. While altruistic and group selective theories could be marshaled to attempt to explain adoption (Rushton et al. 1984), such explanations collapse quickly in the light of the increasing frequency of international and/or transracial adoption (Sahlins 1976). From the view of biological fitness, adoption of non-kin children, particularly by apparently fertile individuals, can be seen as a clear, if highly simplified, maladaptive behavior. (Let it be noted that the author of this entry has himself adopted non-kin children and is unconcerned with the apparent maladaptiveness.)

Conclusion

The evolution of maladaptive behaviors, while difficult to demonstrate unequivocally, often highlights just how dynamic the adaptive milieu can be and the imprecision with which selective pressure is applied to behavior. This is tremendously exacerbated in modern humans in whom cultural evolution now dwarfs biological evolution in shaping behavior, a reality made crystal clear by the phenomenon of reproductive choice. In just two generations, technologies for birth control and abortion of unplanned pregnancies have caused the birth rate to plummet in Western cultures as increasing numbers of individuals choose small families or opt-out of reproduction altogether.

Since these behaviors dramatically reduce biological fitness, they are technically maladaptive. This example shows both the fickle nature of selective pressures on reproductive behaviors and the limits of adaptive explanations for human behavior more broadly.

Coalitional psychology; Intergroup conflict; Male warrior hypothesis

Definition

The male warrior hypothesis claims that the sex-specific adaptive pressures exerted by

recurrent lethal intergroup conflicts in our ancestral past favored the evolution of a cognitive machinery enabling men to form and maintain aggressive coalitions with other males to the end of dominating and exploiting out-groups.

Introduction

War is a gruesome phenomenon. Throughout (pre)history, humans engaging in this brutish activity have brought death, suffering, and destruction to an incalculable amount of their conspecifics. And although some scholars' estimates indicate that the relative impact of wars on human survival and living conditions has been on the decline during the last couple of centuries (Pinker 2011), wars still continue to exert their devastating force today.

From an evolutionary perspective, wars pose a nontrivial puzzle. Why is it that humans are obviously ready and willing to put their lives at risk in collective lethal aggression against groups of conspecifics? Why is it that *Homo sapiens* is among the few species that engage in such murderous campaigns? Why is it, finally, that “[w]hile war may be everyone’s business, it has usually been men’s work,” as Keeley (1996, p. 35) trenchantly put it?

In this entry, we review selected previous literature on all three questions. Our focus, however, lies on sex differences in cognitive mechanisms potentially resulting from the differential adaptive challenges posed to the sexes by the frequent recurrence of violent intergroup conflicts throughout humanization. First, we outline theoretical work on the general cost/benefit structure faced by fitness relevant behavioral strategies in war. Second, we discuss how the main components of the resulting models of human belligerent behavior differentiate humans from many other animals. Third, we ask if human prehistory may have actually met the conditions required for war to entail sufficiently intense selection pressures in order to result in adaptive cognitive sex differences. Finally, we review contemporary evidence for the existence of these differences obtained in controlled psychological experiments, field studies, and surveys.

Theoretical Perspectives on Adaptive Problems Posed by Warfare

Modelling approaches to the evolution of human behavioral strategies commonly start from the assumption that most of our species' evolutionarily relevant time on this planet was characterized by living conditions similar to those of contemporary hunter-gatherer bands and wild chimpanzees. For humans, this means living in relatively small, mobile bands consisting of up to a few dozens of individuals, co-residing with primary and more distant kin, spouses' primary kin, other affines, and unrelated others (for recent demographical estimates, see, e.g., Hill et al. 2011). Multiple bands, then, together form clans, tribes, and ethnolinguistic cultures, which are often characterized by frequent exchanges of members between their subgroups. Most recent models of the evolution of bellicose behavior in humans locate violent conflicts at the between-band level (Choi and Bowles 2007; Lehmann and Feldman 2008; for a comprehensive review see Rusch 2014b).

Theorists have identified the main adaptive challenge that individuals living in such groups face when deciding whether or not to engage in intergroup conflicts as the trade-off that must be made between the potential benefits and prospective risks entailed by waging war. While some authors hold that a decision to participate in collective aggression against out-groups represents a genuinely altruistic act (Choi and Bowles 2007), other authors argue that the cost/benefit structure of war often favors the aggressor directly as long as certain conditions are met (Lehmann and Feldman 2008; Rusch 2014b; Tooby and Cosmides 2010). Relevant to this, one of the most important distinctions is the one between coalitionary defensive aggression, which can occur in the forms of preemptive first strikes as well as retaliatory counterstrikes, on the one hand, and unprovoked offensive aggression on the other. While the evolution of defensive aggression is relatively easy to explain because of its self- and kin-protective function, unprovoked offensive aggression poses a more complex problem (Rusch 2014a). Why should an individual be

willing to participate in aggressing against an out-group, if (i) nonparticipation by this combatant would not substantially lower the chances of victory, if (ii) the spoils obtained in case of victory are shared by all members of the victorious group, and if (iii) the risks entailed by participating are high, potentially even as high as losing the own life.

Theorists have identified multiple factors that can provide solutions to this collective action problem (Gavrilets 2015; Rusch 2014b; Tooby and Cosmides 2010). Apart from the commonplace mechanisms – direct and indirect reciprocity as well as peer-punishment – that can of course also promote group-level cooperation in this context, coalitionary offensive aggression likely differs from other collective action problems in a number of crucial respects. For one, in groups as small as the ones our ancestors lived in, nonparticipation by a single individual quite likely had a significant effect on the outcome of an attack (Johnson and MacKay 2015). This makes every single combatant pivotal for the outcome of a threshold collective action problem, a factor which is known to foster cooperative individual decision-making (Barclay and van Vugt 2015). Second, small deviations from the, arguably unrealistic, assumptions that (i) the spoils of war are equally shared and that (ii) all combatants are equal in their contribution capabilities can already substantially alter the incentive structure of coalitionary aggression. This then leads to positive selection for belligerence in the more battle-ready and/or more privileged individuals (Gavrilets 2015; Gavrilets and Fortunato 2014). Third and finally, an interesting structural asymmetry exists between the risks entailed by offensive versus defensive warfare, caused by the greater strategic flexibility that offenders usually have. Normally, attackers can eventually decide if they want to follow through with a strike or not. If, for instance, a lack of numerical superiority or other situational factors discourage an attack, offenders can retreat safely as long as they are not spotted or ambushed by defenders. In addition, the strategic advantage of surprise is usually on the attackers' side. In effect, these structural advantages often minimize the risks faced by offenders.

In summary, various models and simulations suggest that the benefits associated with coalitional offensive aggression can sometimes outweigh the costs. It must be noted, though, that this likely only pertains to single strikes in hunter-gatherer warfare. The long-term outcome of continuous raiding and feuding between such groups can be quite substantial in terms of mortality risks, as we argue later. Assuming that costs are potentially low in the short term, the question is what the potential benefits of hunter-gatherer aggression are. In order for belligerence to be positively selected for in the long run, these must be large enough to offset not only the relatively small risks of single strikes but also the long-term increases in mortality risks, caused by continuous feuding between bands.

A recent model suggests that there are at least two ways through which aggressors can obtain significant direct and indirect fitness benefits through warring. Building on the conventional assumptions about hunter-gatherer population structure, and explicitly focusing on male combatants, Lehmann and Feldman (2008) showed that both (i) direct fitness increases for males obtained through winning additional reproductive access to females of other groups and (ii) the more indirect effect of increased reproduction of in-group females caused by seizing territory or other valuable resources from out-groups can independently suffice for a positive selection of male belligerence and bravery. Unlike other models, furthermore, Lehmann and Feldman explicitly analyze the role of relatedness between combatants. They find that the potentially high costs of warring can be substantially dampened by high within-group relatedness of male warriors. They show that, although an individual combatant may eventually have to pay with his life for victory over out-groups, the inclusive fitness benefits obtained by him through increased reproduction of his lineage can still offset these costs, even in groups of considerable size.

To summarize, various scenarios favoring a positive selection of belligerence and bravery in intergroup conflict exist in the theoretical literature today. They show consistently that warring may have had adaptive benefits, especially in ancestral men. An important question raised by

these theoretical models of human warfare is why only a handful of species show coalitional aggression (Wrangham 1999).

Nonhuman Evidence

One potential reason for the relative sparseness of intraspecific lethal coalitional aggression in other animals lies in the complex social adaptations that are required for warfare. These include sociality, communality, and advanced capabilities for coordinated action. Furthermore, in order for warring to be potentially beneficial in terms of inclusive fitness, the relatedness patterns resulting from a species' way of living must meet certain criteria. As constantly killing close relatives would obviously result in negative selection against this trait, warring can only evolve if its benefits are more likely to be received by close kin while its costs are borne by more distantly or unrelated individuals. Intense lethal intergroup conflicts occur, for example, in some species of colonial eusocial insects. In these, individuals within colonies are genetically very closely related, while relatedness between colonies is much lower. For most vertebrates, however, relatedness patterns are more complex. In group-living mammals, for example, within- and between-group relatedness crucially depends on residence rules, that is, on the question whether groups frequently exchange individuals and if so which individuals.

For understanding the evolutionary roots of human intergroup aggression, and particularly for the question why it is mostly men who engage in this behavior, residence rules are central. A recent meta-study comparing 135 primate species, for example, found that species in which the dominant sex is philopatric, i.e., species in which the physically stronger sex tends to live together with close relatives while members of the physically weaker sex change round between groups, are more successful at defending their territories (Willems et al. 2013; also see Willems and van Schaik 2015). It seems that close family ties are required to foster the cooperation needed to sustain coalitional aggression in animals. Although no commonly accepted theory explaining the

occurrence of lethal animal intergroup conflict exists yet, residence rules of the warring sex show similar patterns in all mammals for which such conflicts have been documented. Among them are hyenas, lions, wolves, and, of course, chimpanzees, and humans (Wrangham 1999).

Chimpanzee “wars,” in particular, are the best studied cases of nonhuman violent intergroup conflicts. Since Jane Goodall made her famous observations in Gombe National Park, documenting the systematic extermination of all out-group males by a coalition of male chimps over a period of 5 years, many careful field studies have been conducted to understand when – and why – male chimpanzees engage in lethal coalitional aggression and how they might benefit from doing so. Michael Wilson and colleagues recently evaluated the available evidence (Wilson et al. 2014). Analyzing 152 killings in 15 communities, they found that (i) males were the most frequent attackers (92%) and victims (73%) in lethal violence in chimpanzees, (ii) a majority of these killings (66%) involved members of different communities, and (iii) attackers used risk-minimizing tactics (median attacker-to-victim ratio 8:1). In addition, Wilson et al. were able to extract two robust predictors of higher levels of intergroup conflict from their data. Violence increased with population density as well as with the number of males living in the respective communities. They conclude that “patterns of lethal aggression in *Pan* [...] are [...] better explained by the adaptive hypothesis that killing is a means to eliminate rivals when the costs of killing are low” (Wilson et al. 2014, p. 416).

Human Evidence

One might be tempted to extrapolate this “chimpanzee model” directly to humans. Like *Pan troglodytes*, humans are a territorial, group-living species. And, like chimpanzees, *Homo sapiens* often lives patrilocally, that is, groups are often formed around “bands of brothers,” whereas females switch groups through exogamous marriage (e.g., 15 of the 32 contemporary hunter-gatherer societies surveyed recently by Kim Hill

et al. 2011, follow this residence rule; matrilocal: 5, ambiguous/unknown – 12).

Support for the notion that residence patterns, and the kinship structures they induce, are key to understanding human warfare comes from early systematic anthropological work. Adams (1983) analyzed evidence from 67 prestate human societies. He found that in nine of these societies, some forms of active female participation in lethal intergroup violence were documented. Strikingly, all of the nine societies followed residence rules that preclude that women may have to fight relatives in enemy groups. Furthermore, Adams found that patrilocally living societies were more likely to exhibit higher levels of intergroup conflict, as compared to societies following other rules for marital residency. More supportive evidence for the relevance of the “chimpanzee model” for understanding human intergroup conflict was recently compiled by Wrangham and Glowacki (2012). Carefully reviewing the available anthropological literature, they identified many additional similarities between chimpanzee and hunter-gatherer warring. Also in humans, victors often seize territory from defeated out-groups, females are frequently abducted in raids, and attackers mostly use risk-minimizing surprise tactics.

Thus, let us assume for a moment that human prestate intergroup violence resembles chimpanzee warring closely enough to follow a similar fitness logic – an assumption which is certainly debatable (see, e.g., Wrangham and Glowacki 2012 for a comprehensive discussion). The remaining question then is if war in ancestral human populations was frequent and intense enough in order to actually create differential selection pressures on human males and females across evolutionary time.

In terms of absolute numbers, the large-scale wars of the twentieth century have certainly been the deadliest campaigns ever carried out. As Pinker has argued, though, their relative impact on human survival may have been comparably small, taking the size of the world population into account (Pinker 2011). Interestingly, Pinker’s calculations are paralleled in the anthropological literature. Where authors have tried to estimate the

mortality rates caused by lethal intergroup conflict in human prestate societies, they have often arrived at similar conclusions. Keeley (1996), for example, in his reconstruction of the prehistory of war, estimates that in some traditional societies, between 8 and 59% of male deaths may have been caused by war, while this figure lies below 1% for the twentieth century Europe and USA. Also, where data is available, Keeley's estimates indicate that men in traditional societies roughly had a 6.5 times higher chance of dying in war than females (Keeley 1996, p. 196). Similar numbers are reported by Walker and Bailey (2013) who recently analyzed ethnographic reports of 1,145 killings in 44 lowland South American societies. They confirm that attackers in individual raids suffered hardly any casualties and that a major reason for raiding was the capture of women (with ca. 0.6 women being displaced per raid). In addition, they found that a total of 1,045 of these events, representing an average of roughly 28% of all deaths, male and female, were caused by war in this sample. Again, though, men had a substantially higher risk of dying in war than women.

Before we move on to review evidence from recent psychological and social science studies supporting the hypothesis that the potentially high mortality rates caused by war under prehistoric living conditions could have resulted in cognitive adaptations for intergroup conflict, one important point needs to be addressed. As, for example, Gat (2015) elaborately discusses, one should not view human prehistory as a history of perpetual extreme intergroup violence. As Fry and Söderberg (2013), among others, point out, many human societies of all times and regions have most likely also been able to sustain long-term peaceful coexistence with neighboring groups (also see Rusch 2014b; Wrangham and Glowacki 2012). When we speak of psychological adaptations for coalitional aggression and intergroup conflict in the following section, thus, these should be understood as domain-specialized, cognitive mechanisms that are being activated only in adaptively relevant contexts and not (so much) as psychological instincts constantly seeking war as the only solution to conflict.

The Male Warrior Hypothesis

Let us assume, for now, though, that warfare and intergroup conflict have been important selective forces for humans, contributing to a relatively unique human coalitional psychology, with some parallels in other species. Then, it is likely that warfare has shaped the coalitional psychologies of men and women differently. This is the basic thrust behind the male warrior hypothesis which claims that specific cognitive machinery has evolved enabling ancestral men to form and maintain aggressive coalitions with other males with the aim of dominating and exploiting members of out-groups (McDonald et al. 2012; van Vugt and Janssen 2007). What cognitive adaptations constitute this specific warrior psychology, what cues activate it, and how do the sexes differ in the activation of these cognitive mechanisms?

We can distinguish between at least four different coalition mechanisms – or psychological systems – that need to be in place to plan, execute, and be victorious in intergroup conflict. First, *coalition detection* mechanisms need to be in place to be vigilant about potentially, hostile coalitions, remember who is in-group and who is out-group, and assess the strength and formidability of these coalitions. Second, an adaptive warrior psychology requires mechanisms to quickly *recruit allies* to form strong and sometimes sizeable coalitions, pick the right members to form a combat force, and form emotional attachments to these coalitional groups quickly. Furthermore, a cognitive adaptation to assume the identity of a male warrior is helpful (cf. the combat identity hypothesis by Tooby and Cosmides 2010) and so is an above-average interest in the aesthetics of warfare. *Coalitional maintenance* adaptations are needed in order to ensure that coalitions remain together and unified, and they include adaptations for reward cooperative members (e.g., war heroes) and punish defectors (deserters and cowards). Finally, *coalition exploitation* systems allow individuals to time a collective aggressive act and reap the benefits of intergroup aggression by converting the spoils of war into reproductive benefits. Cognitive adaptations that enable individuals to make the right trade-offs between the

risks and benefits of coalitional aggression attack and kill members of out-groups only if potential costs are low and potential benefits are high, dominate and exploit members of out-groups, and morally justify these actions are some examples of exploitation mechanisms that together may constitute this warrior psychology.

Such coalitional systems are likely coupled to specific emotions that allow individuals to make adaptive decisions in the domain of intergroup conflict such as feelings of in-group loyalty, out-group hate, anger toward in-group defectors, admiration of war heroes, etc. Furthermore, these mechanisms are activated by adaptively relevant external cues. Seeing a collection of out-group males together, for example, should activate the coalition detection system more so than seeing a group of out-group females and perhaps especially if the men are (i) physically strong, (ii) in possession of weapons, and (iii) in or near in-group territory. Similarly, individual differences in physical formidability, aggression, social class, age, and social networks likely influence how people trade off the risks of engaging in collective violence. Finally, cognitive adaptations for coalitional aggression, although they may partly overlap with interpersonal aggression, are likely to be activated by distinct, domain-specific cues (such as the formidability and power of the leader of a group; Holbrook and Fessler 2013).

This brings us to consider sex differences. Due to differences in parental investment and, as discussed earlier, differences in physical formidability and co-residence patterns, there is an asymmetry in the costs and benefits of engaging in warfare between men and women. This was especially true in ancestral environments where most forms of intergroup conflict involve physical combat. By virtue of a lower paternal investment, coupled with a stronger physique, it may be adaptive for men under certain conditions to be warriors as this can increase their access to reproductively relevant resources (mates, territories). These conditions are specified in Tooby and Cosmides (1988) risk contract theory of warfare that views warfare as a collective action problem in which free-riding dominates unless (i) there are compensating benefits for cooperators,

(ii) defectors are punished, and (iii) there is a veil of ignorance making it impossible to know who will die and who will survive an attack *a priori*.

Coalitional aggression can be directly fitness enhancing for men as one gains access to women (see above). Other benefits of coalitional aggression are indirect fitness enhancers. That is, by killing or injuring the males of rival groups, these out-groups weaken in strength, and their females may eventually migrate to the in-group (analogous to observed behavior in chimpanzees; Wilson and Wrangham 2003).

Research Support for the Male Warrior Hypothesis

The MWH asserts that men will respond more quickly and strongly to cues associated with intergroup conflict and convert coalitional aggression into reproductive opportunities. This hypothesis does not suggest that all men will always prefer war as an option to manage intergroup relations. Whether or not this warrior psychology is activated depends upon cues that are ancestrally linked to be on the winning side in an intergroup conflict. Second, the MWH allows for individual variation between men in their sensitivity to cues associated with warfare. For instance, warrior behavior may be easier activated in men who are physical stronger, have higher degree of dispositional aggression, possess a higher baseline testosterone, and have larger male kin or friendship networks. Nevertheless, we believe that there should be sex differences in the ease with which different coalitional systems that support intergroup aggression and warfare are being activated. The research literature supports this by and large.

Earlier we reviewed the evidence from primatology and anthropology suggesting selection for male warrior traits. Now we turn to the social sciences. There is an abundance of studies in psychology and other fields (political science, sociology, behavioral economics) that show that men have a lower threshold for engaging in coalitional aggression. First, surveys reveal that

men report having more experiences with competitive intergroup interactions (e.g., team sports) than women (Pemberton et al. 1996). In simulated war games between countries, men as the leader of their nation are also more likely than women leaders to make a preemptive strike against another nation (Johnson et al. 2006). Exclusively male groups make more defective choices in prisoner's dilemmas between groups than all-female groups (Wildschut et al. 2003). Finally, in nationwide opinion polls, conducted in various countries, men are always more supportive of military action as a solution to intergroup conflict (van Vugt 2009). This is ironic, of course, considering the fact that men are also the most likely victims of warfare, but it makes sense if we follow the logic of the MWH.

An indirect test of the MWH involves looking at sex differences in preferences for group-based dominance hierarchies, which is the inevitable outcome of warfare. On an individual measure of this preference, called social dominance orientation (SDO), men score systematically higher than women, even in countries where gender roles are relatively egalitarian such as Sweden (Lee et al. 2011). Importantly, scores on SDO are positively associated with a wide variety of social attitudes and ideologies that tend to legitimize intergroup dominance hierarchies, including racism, patriotism, and the explicit endorsement and support for aggressive wars (Sidanius and Pratto 1999). Men, on average, also display more xenophobic and ethnocentric attitudes than women (Sidanius and Ekehammar 1980), and men are more likely to dehumanize out-group members (van Vugt 2009), which may help ease the psychological discomfort associated with killing or injuring men from rival groups.

The way men and women form and maintain their coalitions also differs. In line with the MWH, developmental studies show that boys form larger, more flexible coalitions than girls, which suggests an ability to form flexible war-size parties (Hawley 2014). Men also identify themselves more strongly with large, tribal groups than women. In one study, researchers showed that men had a more collective self-concept, whereas women had an interpersonal self-concept (Gabriel

and Gardner 1999). They asked men and women to complete 20 statements beginning with "I am. . ." They found that men reported a higher proportion of collective self-descriptors (e.g., "I am a member of a fraternity."), whereas women provided a higher proportion of relational descriptions ("I am best friends with Michelle"). In another study (a summary is reported in van Vugt 2009), we asked men and women what their favorite color was and why. More than twice as many men as women mentioned a tribal association with their favorite color (e.g., "I like the color red because it is in our national flag").

Men are also more motivated to defend their in-group and cooperate with fellow in-group members, particularly when there is an intergroup conflict. In a series of laboratory experiments, we found that men contributed more to a public good for their group when their group was in competition with other groups, rather when they were competing individually. This difference was absent for women. Furthermore, men identified more strongly with their group when it was facing intergroup competition, and again this effect was absent for women (van Vugt et al. 2007). Other studies show that men are also more aesthetically attracted to stimuli depicting intergroup conflict, be it war movies or gangster movies, war documentaries, and books depicting intergroup aggression such as biographies of war heroes (Goldstein 2002; van Vugt 2009).

What about the choice for leaders during episodes of intergroup aggression? Both men and women prefer to appoint men as leaders during intergroup conflicts, presumably because they believe that men fit the physical and psychological prototype of a war leader better. In a public goods experiment, participants who thought the study's aim was to compare how teams of different universities were doing were much more likely to appoint men as their team captains than participants who believed that the study's aim was to compare individual team players in terms of their public good contributions – the majority of them chose women as team captains (van Vugt and Spisak 2008). Various studies, using mock presidential election data, revealed that when people are asked to vote for a president when their

country is facing war, a majority of voters prefer a candidate with a masculine-looking face over a candidate with a more feminine-looking face (Little et al. 2007; Spisak et al. 2012).

Finally, consistent with the MWH and in line with sexual selection theory, there are sex differences in the extent to which warfare is driven by sexual motives. That is, for men, warfare may be a platform on which they can show off their physical skills and psychological qualities as valuable coalition partners or sexual mates. Regarding the latter, recent studies found that women were more sexually attracted to men who had shown bravery in warfare than those who had not (Rusch et al. 2015). This effect was both domain and sex specific. Women were more interested in dating a war hero than a hero in a natural disaster. Furthermore, men were not particularly interested in dating female war heroes, showing evidence for a sex-specific war psychology. In addition, an archive study revealed that male war heroes (Medal of Honor recipients of World War II) sired more offspring than ordinary soldiers – suggesting evidence for reproductive benefits associated with war behavior.

Conclusion

Despite the accumulating evidence for the MWH and specific male adaptations for warfare, a number of contentious issues remain. First, are there specific female cognitive adaptations for warfare? We think there are. Ancestral women's reproductive interests were not served by actively joining in physical combat for the reasons we have already outlined. Nevertheless ancestral women could profit from the extra resources that would be gained by warrior males as long as their group emerged victoriously from combat. Thus, under certain conditions such as a food shortage, women could have encouraged their men to go on a raid. Similarly women may encourage male warrior behavior indirectly through selectively preferring male warriors as their mates (Rusch et al. 2015). Nevertheless, on the whole, we hypothesize that women's psychology is probably more geared toward peacekeeping and peace maintenance

between groups as this serves their reproductive interests best. Not surprisingly, both sexes prefer female leaders to keep the peace in intergroup relations (van Vugt and Spisak 2008). This is not to say that women have not evolved specific cognitive adaptations to deal with warfare. First, out-group men pose specific challenges to the reproductive choices of in-group women. Thus, we expect women to have evolved specific mechanisms that are activated in particular after exposure to out-group male warriors. One such adaptation is rape avoidance, and there are findings suggesting that women are particularly fearful of formidable out-group men versus in-group men (McDonald et al. 2012). Second, it would be in a woman's best interest to opportunistically switch sides once a particular coalition of men emerges victorious after battle. Thus we expect women to have evolved a tend-and-befriend strategy (cf. Taylor et al. 2000) toward victorious out-group men to protect themselves and possibly their offspring from danger. This hypothesis remains to be tested in humans.

Third, the MWH does not preclude the possibility of women to play an active role in combat. Although the notorious army of Amazon warriors is likely a myth, women do sometimes join a fight. Female warrior behavior seems to be driven by factors such as the size of the war coalition needed in battle. For instance, Israel is surrounded by a number of countries that are hostile to Israel, and not surprising, it is also the country that has the largest portion of active female soldiers in service (Goldstein 2002). Thus, although women may not be predisposed to be warriors, there may be critical conditions – such as the overwhelming coalition size of the out-group – that override these evolved tendencies. In addition, although offensive coalitional actions such as raids and ambush killings are largely the domain of men, this may be different when a group is defending itself against a hostile out-group.

A final challenge is what specific cues trigger this male warrior psychology and if there are individual differences. Cues of out-group males teaming up together should activate this warrior psychology and probably more so when this male coalition is sizeable in numbers and has a

physically formidable leader. Men should be better at detecting coalitions than women, being able to remember better to which tribal groups a person belongs (Kurzban et al. 2001). Resource scarcities should probably activate male warrior tendencies and so does the presence of young, fertile out-group women. Finally, one's own physique and personality might matter. That is, warrior tendencies are easier to activate in men who are physically formidable, have high base levels of testosterone, and have a fearless personality.

Male Adaptations to Assess Fighting Ability

Aaron Sell
Griffith University, Mount Gravatt, QLD,
Australia

Synonyms

Formidability assessment

Definition

Adaptations for assessing fighting ability are perceptual mechanisms designed by natural selection to predict the victor of future bouts of aggression.

Introduction

Nonhuman animals are known to have evolved strategies for the assessment of fighting ability. In short, they “size up” their opponents before and during aggressive contests so as to make more prudent decisions about the fight. Evolutionary psychologists have now gathered evidence that humans also have this competence as a result of several evolved adaptations that extract cues from the body, face, and voice primarily of adult men. This entry reviews the logic of animal assessment and the data showing that humans have evolved adaptations for estimating fighting ability. It also explores some of the new data identifying which cues are used to estimate fighting ability.

The Evolutionary Function of Fighting Ability Assessment

First year psychology students are often told that there are three kinds of neurons: motor neurons to contract muscles and generate behavior, sensory neurons to respond to environmental stimuli, and interneurons to store information and connect the other two. This basic observation reflects a

crucially important point about evolutionary biology: that the function of the nervous system in animals is to make muscle movement (i.e., behavior) contingent on environmental cues. The interneurons, which make up the bulk of the human brain, function to compute and store information that is then used to process sensory data and coordinate muscle movement (along with a contingent of other adaptations, e.g., the endocrine system). Analyzed from the viewpoint of evolutionary biology, the brain is literally a computer that runs behavioral programs that are contingent on calculations made about information coming from perceptual systems.

Perceptual systems, then, will be designed to perceive only a narrow slice of reality, particularly the cues that enabled behavioral systems to be most efficient at overcoming adaptive problems. For an organism of a social species, these adaptive problems would include many aspects of their fellow conspecifics. For example, an individual's access to food, territory, water, mates, and information will often depend on the behavior of others. Therefore, we can expect that natural selection would have designed social species with many perceptual adaptations that function to recognize, categorize, evaluate, and store information about other animals. For example, animals are generally designed to recognize their own species, distinguish their biological kin from non-relatives, evaluate the quality of potential mates, and estimate a conspecific's fighting ability (Alcock 2005; Arnott and Elwood 2009).

Why Do Nonhuman Animals Assess Fighting Ability?

It is difficult to know why animals would assess fighting ability if one does not know why animals fight. Fortunately, evolutionary biologists understand the basics of animal aggression quite well: aggression is a tool designed by natural selection that enables one organism to disrupt the functional integrity of another organism in ways that enable the aggressor to solve an adaptive problem. For example, a lion requires large numbers of calories to survive. The meat of a gazelle contains these calories, but gazelles have evolved to flee from lions. Lions then evolved neck-biting behaviors

that disconnect the gazelle's respiratory and circulatory system which causes loss of function and renders the prey inert so that the lion can consume it.

Excepting predator–prey relationships, conflicts between conspecifics rarely require that one's opponent be killed. Conflicts between individuals of the same species are often over territory, food sources, and mates. Such fights can be “won” if an organism disorders the functional machinery that constitutes the body of the other (i.e., injures them). Thus, aggression is frequently used during these conflicts (Alcock 2005). Typically, the larger more powerful animal will win these conflicts, a pattern found in dozens of species. While physical size and strength contribute to fighting ability, in species where size is less relevant to the likely outcome of a fight, different traits will determine the winner, e.g., weapon size, physical condition, and tactical position (Arnott and Elwood 2009). Assessing these traits is therefore of crucial importance. Any animal that can assess, in advance, whether it is likely to win a conflict can make more prudent decisions about whether to instigate, escalate, or retreat during a fight. Therefore, one would predict that natural selection has designed adaptations that perceive cues of fighting ability in others and in oneself and use those estimates to modulate between different behavioral strategies before, during, and after a conflict.

Evidence shows exactly that (Arnott and Elwood 2009; Huntingford and Turner 1987). Many species estimate fighting ability from perceptual cues (e.g., vocalizations, visual inspections) but also from aggression itself. Given the importance of assessing fighting ability, and the selective damage of an erroneous estimate (i.e., retreating from a fight one could have won and commencing in a fight that one loses), it should not be surprising that natural selection has shaped complex mechanisms for these estimates. For example, domestic hens use a kind of Bayesian reasoning when watching two conspecifics fight, so that when one hen defeats another, the hen watching the fight will credit the victor with greater fighting ability if the opponent they defeated was estimated to be a good fighter (Hogue et al. 1996).

If humans have had a history of aggression, then we should expect nature to have equipped them with adaptations that assess fighting ability as well.

Are Humans Likely to Have Fighting Ability Assessment Mechanisms?

The ancestors of modern humans were highly aggressive (Pinker 2011). In past environments (in which the human mind evolved; see Tooby and Cosmides 1990), being able to accurately estimate the fighting ability of another human would have provided a powerful reproductive advantage. Therefore, one would predict on first principles that humans are designed to accurately assess fighting ability in conspecifics (Sell et al. 2009).

Crucially, human aggression is usually deployed against and by males. In this way, humans conform to a widespread mammalian pattern in which the sex that invests less in offspring competes more aggressively for access to mates and the resources used to keep and acquire them (Daly and Wilson 1983). One result is that the male human morph has been designed for combat at the expense of longevity. For example, compared to women, men have larger bodies, higher basal metabolic rates, larger hearts, better heat dissipation, more hemoglobin, more muscle, less fat, denser bones, and much more upper body strength (see Sell et al. 2012). These differences – and others – demonstrate that men have been engaged in aggressive competition for many generations. Finally, while most aggression is deployed between males, research shows that female mate choice is also influenced by factors related to fighting ability (see Collins 2000; Fink et al. 2007; Hughes et al. 2004). This would contribute to the sex differences in frequency of aggression, but also mean that women would also use mechanisms for assessing male fighting ability. Taken together, this chain of reasoning leads to three predictions: (i) that humans have likely evolved fighting ability assessment mechanisms, (ii) that those mechanisms should be fine-tuned to estimate male fighting ability, and (iii) that both men and women should have these mechanisms.

Adaptations for Assessing Fighting Ability

The primary function of assessing fighting ability is to predict the likely outcomes of fights in a way that minimizes the cost of fighting to the perceiver. Due to the nature of prediction, there is a trade-off between the accuracy and cost of the assessment. For example, one can estimate fighting ability very well by fighting someone to the death, but that comes at a great price. On the other side of the trade-off are perceptual estimates of fighting ability that are energetically cheap and do not risk injury but provide – presumably – less accurate assessments.

Because of their cheap nature, assessments in the animal kingdom frequently start with long-distance perceptual scans for cues that predict fighting ability. It is difficult to gain experimental control over realistic visual images and not possible to ask most animals whether a given opponent looks formidable, but evolutionary biologists have used controlled experiments to test whether animals use visual assessments of fighting ability. Results have shown across a number of animal species that visual assessment provides animals with information about fighting ability (see Arnott and Elwood 2009).

If there exist visual cues of fighting ability in humans, particularly human males, one would expect natural selection to have designed assessment mechanisms for the perception of those cues. Evidence supports this.

Visual Inspection of the Body

Humans have high functioning visual systems, and so it could be predicted that natural selection would tailor this system in particular to respond to any perceptible cues of fighting ability in the bodies of other humans – especially males. Such a prediction would require, however, that there actually be visually accessible cues of fighting ability.

How Could One See Fighting Ability in the Body?

A first principled analysis of human combat suggests that an individual's fighting ability is dependent in large measure on his ability to exert force

against another individual. Humans have no naturally produced poisons, toxins, inks, pincers, horns, or other ostentatious weaponry and fight instead with grips, punches, chokes, bites, and artificially constructed weapons. Such methods rely primarily on upper body strength for the application of force; indeed, no prehistoric weapon has ever been found that relied primarily on lower body strength for the production of force. While core and lower body strength is far from irrelevant, the ability to deliver a strike, choke, or hold will depend heavily on upper body strength. Therefore, one large component of human fighting ability will be upper body strength (see Sell et al. 2009). This analysis is supported by the fact that upper body strength is a highly sexually dimorphic trait in humans, with the more aggressive sex (males) having approximately 75% more of it (Lassek and Gaulin 2009).

Can Humans Visually Assess Fighting Ability?

According to this logic, males with physically stronger upper bodies should be readily perceived as such and be inferred to be better fighters. A team of evolutionary psychologists at UCSB conducted the first test to measure just how accurate assessment of physical strength is from visual inspections of the body (Sell et al. 2009). Sell and colleagues measured the upper body strength of 59 male subjects on four weight-lifting machines and took full body, shirtless, photographs of the subjects standing next to an experimenter (for size comparisons). Raters were then shown the photographs and asked to rate the subjects on how physically strong they appeared. Other raters were asked to rate the photographs on how “tough [he] would be in a physical fight.” Results showed that a static two-dimensional photograph of a man contained enough information that raters could predict about half of the variance in weight-lifting strength. Given that there was undoubtedly error in the lifting strength measure, that the photographs were static, and that the sample was truncated to primarily of young college-aged men, this 50% is certainly an underestimate of how much variance in physical strength can be assessed visually. Importantly, ratings of physical strength were identical to ratings of “toughness”

($r = .96$). This supports the view that upper body strength is a crucial component of fighting ability; in the minds of the raters, they were the same variable.

There is also evidence of specialized design in the assessments that supports the hypothesis that humans possess evolved fighting ability assessment mechanisms. For example, regression analyses showed that ratings of “toughness” and “physical strength” were tracking actual weightlifting strength more so than height or weight. While taller subjects were credited as being tougher (std. Beta = .29), this effect was much smaller than actual strength (std. Beta = .49). Body weight, once its correlations with lifting strength and height were statically controlled, was no longer related to ratings of fighting ability at all (indeed it was negative in some analyses). In other words, raters were not just picking larger males along easily perceptible dimensions (e.g., size, height) but were extracting cues of actual upper body strength, crediting males additionally if they were tall, and penalizing them slightly for being overweight. Additional analyses revealed that subjects were responding to cues of upper body strength over lower body strength. In other words, their ratings were zeroing in on the particular kind of strength that is used in ancestral human aggression.

What Are the Cues of Fighting Ability in the Body that Are Being Estimated?

The question of what actual cues were being perceived has remained largely unanswered. Morphometric measurements of the subjects were taken, and analyses showed that biceps circumference was the single best predictor of lifting strength, but no bodily measurement or combination of measures predicted upper body strength as well as ratings of strength did. It can be concluded, however, that height is being assessed (and taller men are being credited as better fighters), but the ability to accurately assess upper body strength visually is largely independent of height assessments. More research, preferably experimental research, will need to be done to isolate the visual predictors of fighting ability in men.

Is the Visual Assessment of Fighting Ability More Accurate on Male Targets?

Sell et al. (2009) replicated the assessment of upper body strength on a second sample of college students that included both males and females. This necessitated less naturalistic stimuli, e.g., female subjects wore standardized white T-shirts rather than being photographed shirtless, and upper body strength was assessed using proxy measurements validated on the gym sample, specifically, a portable chest compression measure, self-report, and flexed biceps circumference. Unfortunately, the fact that most of female subjects' upper bodies were obscured made it impossible to meaningfully compare the accuracy of assessing upper body strength across the sexes. Raters could still assess female upper body strength from photographs, accounting for approximately 25% of the variance in the composite strength measure. This was less accurate than ratings of male upper body strengths, but little can be made of this difference.

Visual Inspection of the Face

Sell and colleagues (2009) also speculated that humans might assess fighting ability via visual inspection of the face. This was based on three lines of reasoning: (i) there is a precedent in that the human brain is known to possess specialized perceptual mechanisms for processing many kinds of information from the face, (ii) cues of the upper body in ancestral environment may have been obscured by clothing, vegetation, carried objects, tactical cover, and so on, selecting for visual assessment of the face, (iii) decisions that make use of estimates of fighting ability would sometimes need to have been made rapidly, and (iv) the face may contain additional cues of upper body strength not present in the upper body itself (see Sell et al. 2009 for references). Indeed, Fink et al. (2007) had already shown evidence that a man's handgrip strength (a measure of upper body strength) was correlated with ratings (by females) of “dominance,” “masculinity,” and “attractiveness” once one controlled for age and body weight.

How Could One See Fighting Ability in the Face?

There are a number of reasons that the skeletomuscular structure of the face would be relevant to combat. Perhaps of most relevance is that the face is a frequent target of strikes and that strikes to the face can render an individual unconscious. There is paleontological evidence that the structure of the human face (which is markedly different than that of chimpanzees) has been tinkered by natural selection to absorb blunt force trauma more efficiently (Carrier and Morgan 2015). The possibility that differences in human faces track bite strength is also being investigated (Sell et al. 2014). These lines of inquiry suggest that faces are – to some extent – relevant to combat and therefore that different faces could be more or less proficient at aggression. Another possibility is that the face contains cues of fighting ability but that these cues are not themselves causally related to fighting ability. For example, the “masculinity” and “dominance” perceptions of a face often track testosterone levels in the body (Penton-Voak and Chen 2004).

Can Humans Visually Assess Fighting Ability From the Face?

As mentioned above, research demonstrated that handgrip strength in men was tracked by ratings of dominance by female raters (Fink et al. 2007). Sell and colleagues extended this analysis by including both sexes as raters and subjects, using more extensive measures of upper body strength, and including two non-Western cultures: the Tsimane Indians of Bolivia and a group of Andean pastoralists (2009). The correlations between ratings of strength and actual upper body strength are recreated in Table 1.

Results showed that both male and female raters could assess physical strength from a visual inspection of a static two-dimensional photograph

of a man with enough accuracy to predict about a quarter of the variance in upper body strength. Again, given the static nature of the photographs, the imperfect measures of fighting ability, and the limits of the sample, this likely underestimates the accuracy of assessment. Furthermore, accuracy was not diminished at all when assessing males from unfamiliar cultures (which also had no variance in ethnicity). Assessments of strength from female faces were less accurate when rated by either sex and (unlike full body ratings) were not compromised by sex differences in clothing. This suggests that both males and females are all well calibrated for assessing male strength.

Like assessments of the full body, assessments from the face were not overly dependent on estimates of height or weight. Ratings of physical strength from the face also tracked upper body strength over lower body strength; an impressive feat given is that neither the upper nor lower body was visible. This is consistent with two possibilities: either cues in the face that are being assessed are by-products of development or the cues arise because the developmental systems that give rise to upper body strength also coordinate functional components of fighting ability in the face (e.g., blunt force resistance).

One limitation of the Sell et al. studies is that they rely only on upper body strength as a measure of fighting ability. While upper body strength is undoubtedly a large component of fighting ability, there are many additional sources of variance in the ability to fight. Ideally, researchers would use actual fights to measure fighting ability, but this presents a sizeable ethical problem. Fortunately, mixed martial arts (MMA) – in which individuals fight with relatively few restrictions – has become a popular sport with enough data for analysis. Several researchers have looked at mixed martial arts contests and tested the ability

Male Adaptations to Assess Fighting Ability, Table 1 Accuracy of fighting ability assessment from face (From Sell et al. 2009)

	Gym sample (males)	Tsimane males	Andean males	UCSB students (males)	UCSB students (females)
Correlation with upper body strength <i>r</i> (<i>p</i>)	.45 (.0003)	.52 (.0001)	.47 (.01)	.39 (.00001)	.21 (.01)

M

of subjects to predict winners based on photographs of the contestants' faces. While these fights are undoubtedly better measures of fighting ability, they unfortunately severely truncate the sample to only the best hand-to-hand fighters in the world and further truncate within samples by weight class.

With those limitations in mind, there have nevertheless been several published studies showing links between features of the face and combat performance in MMA.

Anthony Little and colleagues (2015) produced arguably the most direct test of whether fighting ability can be estimated from the face by showing the faces of MMA fighters to subjects who then attempted to pick the winner of the fight. Results showed that they could do this with better than chance accuracy. These faces were also rated for strength by different subjects, and the results indicated that MMA fighters with stronger-looking faces than their opponents were more likely to win.

One of the first studies to look at MMA fighters was done by Třebický and colleagues (2013) who looked at samples of MMA fighters and correlated their recorded fights against ratings of aggressiveness and fighting ability from photographs of their face. Results were mixed because weight was confounded with ratings of fighting ability (another limitation of MMA studies is that the fighters shed body fat in order to qualify in as low a weight class as possible, leading to an artificially high correlation between body weight and muscle mass). Perceived fighting ability was only predictive of fighting records among heavy-weight fighters who had no weight restrictions.

Another way to mitigate reliance on upper body strength as a measure of fighting ability is to use peer ratings. Doll and colleagues had fraternities give peer ratings of each other's fighting ability. They then had facial photographs taken and rated by strangers on "dominance." Results showed that these dominance ratings tracked peer ratings of fighting ability (Doll et al. 2014). And while dominance and fighting ability are not the same construct, ratings of dominance and ratings of fighting ability are very highly correlated (Toscano et al. 2014).

What Are the Cues of Fighting Ability in the Face?
Compared to research on body assessments, there are many research studies that hint at the cues that indicate fighting ability in the face.

Třebický and colleagues (2013), in their study of MMA fighters, found that aggressive-looking faces had larger chins, more prominent eyebrows, and a larger nose. Zilioli and colleagues (2015) analyzed a sample of several hundred MMA fighters and showed that having a face that was wider but shorter (i.e., facial width-to-height ratio, fWHR) was predictive of having more wins, a greater percentage of wins, and lasting for more matches in the competitive Ultimate Fighters Championship circuit. Artificial faces made to have wider faces were also rated as physically tougher than narrow faces. Toscano et al. (2014) used natural and artificial faces rated on strength and dominance. They found that low brows, large chins, wide noses, and narrow mouths were rated as stronger. Windhager and colleagues (2011) showed that physical strength (i.e., handgrip, shoulder width) was predictive of rounder faces, wider eyebrows, and a more prominent jaw, though the sample size was rather small for such analyses ($n = 26$). Windhager and colleagues also found that perceived dominance was the result of a wide lower face, smaller lips, shorter nose, and smaller eyes.

Research on the design of the anger face illustrated seven features of the face that are used when assessing physical strength. Sell et al. (2014) proposed that the anger face itself is a coordinated modification of cues in the face that indicate fighting ability. They had computer-generated faces rated for physical strength and showed that each of the seven major components of the anger face – independently – increased perceived strength. The features included: a lower browridge, higher cheekbones, wider nose, higher mouth, thinner lips, protruding lips, and larger chin and chin bun. While this demonstrates that these features do influence ratings of fighting ability, they did not demonstrate that these particular features are indeed present in better fighters.

Is the Visual Assessment of Fighting Ability More Accurate on Male Targets?

Sell et al. (2009) found that both males and females were more accurate at estimating male strength from photographs of the face. Most studies of fighting ability assessment, however, do not look at female faces, so this effect should be replicated before strong conclusions are drawn. Female MMA fighters are becoming more common, but so far no researchers have published work on whether female fighters’ records are predictable from facial features.

Cues of Fighting Ability in the Voice

Unlike the structure of the face, which may play some causal role in fighting (be it through biting or blunt force trauma resistance), it is unlikely that the acoustic properties of the human voice played a direct causal role in resisting or inflicting damage on others. Nonetheless, there are several reasons to believe that the voice may contain indicators of fighting ability (see Sell et al. 2010). Firstly, there are numerous animal precedents showing that vocal qualities not only indicate size and fighting ability but that animals evolved to respond to those qualities (see Huntingford and Turner 1987; Sell 2012). Secondly, research demonstrates that women’s mate choices are highly tuned to characteristics of the male voice, which indicates that there are cues of some desirable traits in the voice (Collins 2000; Hughes et al. 2004; Puts 2005). Finally, testosterone modifies the voice of males in ways that generate large sex differences in vocal characteristics (Dabbs and Mallinger 1999). Given that testosterone plausibly affects fighting ability (Bhasin et al. 1996), it is plausible that fighting ability itself can be predicted from cues in the voice.

Can Humans Assess Fighting Ability From the Voice?

There is good evidence that some physical characteristics associated with fighting ability can be assessed from the voice. Acoustic research in perceptual psychology has a long history – over 30 years – of testing subjects’ ability to estimate body size from the voice. The results depend partly on the nature of the voice samples and often have samples too small to detect the typical effect sizes reported elsewhere, but overall the research demonstrates the ability to assess height and weight from the voice (see Sell 2012 for review).

More evolutionary-minded researchers looked at aspects of the phenotype more closely linked to fighting ability rather than just height and weight. For example, Hughes et al. (2004) showed ratings of attractiveness predicted shoulder-to-hip ratio (a measure believed to be predictive of upper body strength).

Sell and colleagues (2010) tested the ability to assess fighting ability more directly by measuring upper body strength and gathering voice samples from four cultures: male and female college students from the USA and Romania, the adult male population of a Tsimane Indian group, and an adult male group of Andean pastoralists. Voice samples were done in the subjects’ normal speaking voice reading or repeating a standardized phrase in their native language. Correlations between measures of upper body strength and ratings of strength are reported in Table 2 and illustrate that males and female can accurately assess upper body strength from the voice.

Again, accuracy was not diminished at all when assessing males from unfamiliar cultures. Assessments of strength from female voices

M

Male Adaptations to Assess Fighting Ability, Table 2 Accuracy of fighting ability assessment from the voice (From Sell et al. 2010)

	Males					Females	
	USA-1	Tsimane	Andean	USA-2	Romania	USA-2	Romania
Correlation with upper body strength $r(p)$	.45 (.001)	.35 (.02)	.46 (.04)	.51 (.001)	.48 (.001)	.26 (.07)	.32 (.08)

were generally less accurate when compared to the males of the same culture. As with photos of the face, additional analyses showed that both males and females were well calibrated for assessing male strength and that the assessments were not highly dependent on estimates of height or weight. Furthermore, because photographs of the subjects were available as well, regression analyses were able to be run that demonstrated that assessments from the voice were not redundant with assessments from photographs. In other words, having access to a man's voice as well as visual information about his body enabled a more accurate rating of fighting ability than either did alone.

Other research has failed to find a link between various covariates of fighting ability and ratings of dominance or strength. Doll et al. (2014), for example, found no relationship between dominance ratings of male voices and their acquaintance-rated fighting ability. And numerous studies failed to show that subjects could assess height or weight reliably (see Sell 2012).

Regardless, the weight of the evidence is that various body characteristics associated with fighting ability are linked to different acoustic cues that are produced in the normal speaking voice and spontaneously extracted by the human auditory system (see Sell 2012 for review).

What Are the Cues of Fighting Ability in the Voice? Researchers have suggested numerous acoustic traits that could covary with fighting ability, body size, or the assessments thereof. While some progress has been made, no one has produced an acoustic analysis that can be shown to mimic the ratings of human responses. Regardless, there has been data that demonstrates some recurrent relationships between acoustic variables and various body measurements. The most common are *fundamental frequency* and *formant dispersion*.

F0 – Fundamental frequency. Fundamental frequency is the result of vocal fold vibrations during speech and is not physiologically necessarily related to body size or strength. The vocal folds do, however, respond to testosterone and are highly sexually dimorphic due to a rapid thickening in adult males. The result is that adult men

have much lower F0s (i.e., lower “pitched” voices). F0 clearly distinguishes men from women, and adolescent men from adult men (Hodges-Simeon et al. 2014), but generally does not highly distinguish strong from weak men or large from small men. Nonetheless, experimental manipulation of F0 does show that listeners respond to it and (mis)attribute greater size and strength to men with lower pitched voices. These results were found in Sell et al. (2010) for all tested cultures. F0 did not predict physical strength but did predict ratings of strength (see also Rendall et al. 2007). In her definitive meta-analysis on vocal correlates of body size, Pisanski and colleagues (2014) found that F0 explained less than 2% of the variance in height and weight within adult within-sex samples.

Df – Formant dispersion. Formant dispersion was first proposed by Fitch (1997) who defined it as the averaged difference between adjacent formant frequencies and is – in theory and in practice – linked to the length of the vocal tract and therefore likely covaries with height and perhaps other physical traits. It is an acoustic variable known to predict body size in a number of non-human species (see Pisanski et al. 2014). Sell et al. (2010) found in a single sample of recorded vowel sounds that Df did not predict physical strength and could not account for the accuracy of strength assessment. It did predict height marginally. This is consistent with the larger literature that shows various measures of variance in formant position showing weak negative relationships with height (Pisanski et al. 2014).

Pf – Formant position. Formant position was first introduced by David Puts and colleagues (2011) as a new way of measuring formants which results in a more sexually dimorphic measure similar to formant dispersion (see Puts et al. 2011 for details). Puts and colleagues showed that Pf predicts upper body strength in both a US sample and a sample of Hadza men from Tanzania (correlations were $-.26$ and $-.23$, respectively, though given the smaller sample size, the Hadza correlation was not significant).

While the details of the acoustic variables are still under study, there is good evidence that

speaking voices contain cues of fighting ability and that people extract and use them to estimate it.

Self-Assessment of Formidability

Without an accurate estimate of one's own fighting ability, knowledge of another's would be of little functional use. Thus, it is expected that animals and humans have mechanisms for assessing, tracking, and updating their own fighting ability. Direct evidence comes from experiments such as Richard Alexander's work with fighting crickets (1961). When crickets were allowed to physically dominate "dummy" crickets (i.e., artificial animals created by biologists to resemble crickets), the victors become more likely to challenge live competitors in the future, demonstrating that victory is tracked in the brain of the winning animal as an indicator of the likelihood of future success. Edmonds and Briffa (2016) recently showed that some animals not only track their own fighting ability, but different aspects of their fighting ability. When hermit crabs had the effectiveness of their shell knocking strikes reduced (by buffering their shell), they compensated by switching to an uncompromised and lesser used tactic – rocking their opponent's shell. This switch suggests that the crabs are estimating the effectiveness of at least two kinds of strikes and updating this estimate continuously.

The phenomena of "badges" – in which animals signal their fighting condition via coloring or markings – also demonstrates that animals maintain an internal representation of their own fighting ability (Alcock 2005).

The most direct evidence that humans store representations of their own formidability is data showing very high correlations between objective measurements of physical strength and subjects' own self-assessments (Sell et al. 2009). Similar research shows that individual's self-ratings of fighting ability correspond closely to those of their peers, i.e., men and their peers agree on who are the best fighters (Doll et al. 2014). The mechanisms which humans use to do these computations, and their computational structure, remain to be mapped.

Future Research: Aggression as Assessment

From an evolutionary point of view, perceptual assessment is low cost but low accuracy. There are many factors that determine an individual's fighting ability that will not be vulnerable to a visual or auditory analysis. For example, the following factors are sexually dimorphic and arguably causally related to fighting ability: reaction time, basal metabolic rate, mental rotation and speed of spatial visualization, throwing accuracy, history of combat practice, heat dissipation rates, hemoglobin levels in the blood, heart size, and lung capacity (see Sell et al. 2012). These traits could still be estimated if the developmental programs that gave rise to them were, for example, coordinated by pubertal testosterone levels which left perceptible cues in the voice and face. Regardless, these are imperfect estimates of imperfect indicators.

More accurate estimates of fighting ability can be gained through actual fighting. Evolution has designed mechanisms in many nonhuman animals for engaging in ritualized aggression or "conflicts of assessment" (Huntingford and Turner 1987; Alcock 2005) that function to enable two animals to assess fighting ability during a given conflict. For example, the cichlid fish studied will progress through a series of aggressive stages starting with perceptual assessment (e.g., parallel swimming), to coordinated displays of body size and strength (e.g., "tail-beating" in which the fish take turns shaking their bodies at each other to make waves), and finally actual contact aggression (e.g., mouth-locked wrestling) (Enquist et al. 1990). By following the rules of this "ritual," both animals are able to assess fighting ability through forms of aggression that are less likely to result in injury for both contestants.

Such rituals are found among humans as well (Pinker 2011). A more detailed and thorough treatment of ritualized aggression in humans is needed and will likely be able to explain core concepts in human aggression such as honor, "fair fights," sports, and sportsmanship.

Conclusion

In conclusion, given the long history of human aggression – particularly between males – there is a strong theoretical reason to believe that natural selection would have favored mechanisms for estimating male fighting ability. The computational structures of these mechanisms are now being mapped. Evidence shows that both men and women can estimate aspects of fighting ability from cues in the body, face, and voice. While the exact nature of the cues is still being explored, there is evidence that cues of fighting ability in the face include aspects of the brow, the width-to-height ratio of the face, nose and mouth size, and jaw size. Cues of fighting ability in the voice likely include aspects of formant position that result from the length of the vocal tract and possibly fundamental frequency. Future research will likely show that a great deal of human interpersonal aggression is also designed for assessment.

Male Coalitions for Hunting

Sasha Javadpour and Amy Jia Ying Lim

Synonyms

Coalitions; Cooperation

Definition

A coalition is a complex social construct that requires a balance between competitive and cooperative behaviors.

Introduction

People coming together to form coalitions, or temporary alliances, for the intent of attaining a shared goal has been observed since the Pleistocene Epoch (Colarelli et al. 2006; Sugiyama et al. 2018). Human ancestral preferences for protein- and fat-rich foods meant that ancestral hunter-gatherer tribes had to form hunting coalitions to capture larger and faster prey, which offered these nourishments, that would have eluded the lone hunter (Boesch 2002). Because coalitional hunting was a highly complex and risky endeavor, the task of hunting fell primarily on males, who possess physical capabilities and psychological adaptations that facilitated the success of a hunt (Bailey et al. 2013), including the physiological build and strength of a male, the tendency to form instrumental relationships, and their propensity toward risk-taking behavior (Apicella et al. 2017; Tanner 1990).

Today, even though hunting coalitions are less common, male coalitions are still evident in

activities involving group-level competition such as warfare and team sports (Apicella et al. 2017; Geary et al. 2003; Lombardo 2012; Van Vugt et al. 2007). Given the extent of the topic, this chapter will limit its review to how ancestral hunting coalitions facilitated the development of certain adaptations that conferred the male certain advantages in cooperative intergroup situations.

Physical Capabilities for Hunting

According to the evolutionary neuroandrogenic theory, during the gestation period of the male fetus, the Y chromosome initiates a series of biochemical actions that lead to significant spikes in testosterone production which results in an androgenized brain (Ellis 2011). Such a development accounted for greater physical size and strength, agility, bone density, and musculature – features that made males better suited for the physical requirements of hunting as compared to females (Geary et al. 2003). Since males with these traits were better able to provide, such indicators of strength also came to be perceived as indicators of a healthy and resourceful mate. Hence, these traits were maintained via sexual selection as they were preferred and sought after by the opposite sex (Apicella 2014; Escasa et al. 2010).

Many of today's sports parallel the skills required in hunting, such as the chasing of the ball in football or the aiming and throwing of a basketball (Lombardo 2012). Even with the surge of female athletes, sport remains primarily dominated by males with male athletes generally outperforming their female counterparts (Lombardo 2012), suggesting the evolved physical skills and qualities that males possess (de Block and Dewitte 2009).

Adaptations for Hunting

Underlying a hunting operation is an intricate system that maximizes cooperation while minimizing intragroup competition, implying that males would have evolved several psychological adaptations that drove these behaviors.

Hunting is a complex skill. The hunter must come to understand the prey being hunted; he must have tactical awareness of other group members, and the understanding of their own role within the group (Boesch 2002). Only then would the group be able to execute complex actions such as fanning out, chasing, distracting, ambushing, surrounding, and capturing (Boesch 2002). In these activities, members would have to cooperate. Doing so would increase the probability of a successful hunt and increase the ability of the coalition to capture a wider variety of prey that differ in size and speed at lower risk of injury and lower cost of energy, as compared to a lone hunter or an uncoordinated group (Bailey et al. 2013). The reduced risk and energy lost per hunter would also mean that hunting could be conducted more frequently to attain larger amounts of food resources to support a larger community (Bailey et al. 2013). The ability to form coalitions for hunting, therefore, carried a significant survival benefit for the group.

Males continue to demonstrate higher tendencies to form large groups that are instrumental in nature and goal oriented (Geary et al. 2003). In organizations today, males continue to show a tendency to form instrumental workplace relationships that revolve around a shared interest or activity, while females were more likely to form workplace relationships that are more communal and support oriented (Morrison 2009). This phenomenon can already be observed in boys as young as 5 years who would form large social groups that display dominance hierarchies and role differentiation, while girls tend to form smaller dyads that focus on intimacy, emotional support, and guidance (Eder and Hallinan 1978). Boys have also been observed to discourage intragroup aggression when faced with intergroup competition, which suggests that when confronted with an external threat to the group, the mechanism for intragroup competition would be suspended in exchange for the formation of a coalition to address the external threat (Colarelli et al. 2006). This could be suggestive of adaptive mechanisms that have evolved to maximize cooperative behavior and minimize competitive behavior in males.

Risk-Taking Propensity

Coalitional hunting, although risky, was a highly rewarding venture (Apicella et al. 2017). Risk-taking behavior in hunts offered opportunities to attain larger payoffs and were selected for, given that it maximizes the potential resources an individual could bring home (Apicella et al. 2008). This innate propensity for risk-taking is evident in activities males partake in today. A study of 1200 children from Colombia and Sweden found that boys as young as 9 years old showed a greater preference for the all-or-nothing coin flip option over the slow incremental option, which demonstrates a greater propensity for risk-taking behavior (Cárdenas et al. 2012). Men were more likely than women to engage in multiple domains of risk-taking behavior such as in between-group competition, in within-group competition, and in the context of reproduction (Wang et al. 2009). Men were also more likely to make risky financial decisions that offer a larger payoff (Apicella et al. 2008). This risk-taking propensity, combined with competitive predispositions, has been cited as one possible reason for why men continue to occupy top positions in the majority of organizations (Croson and Gneezy 2009).

Conclusion

Over the course of human history, males have evolved physical capabilities and adaptations for cooperative and competitive behaviors and the propensity to engage in risk-taking as a consequence of hunting coalitions. Such evolved mechanisms remain in today's world even though the need for hunting has reduced. Taken together, this evolutionary perspective can offer a novel framework for utilizing evolved mechanisms in modified settings to enhance productivity, teamwork, and healthy competition in the modern workplace, while simultaneously identifying and correcting dysfunctional environments (Colarelli et al. 2006; Yue et al. 2019). With the rising influx of women into the workforce, this evolutionary framework may, ultimately, aid organizations in fully utilizing the increasing diversity in the modern world.

Male Counter Strategies to Cyclic Shifts

Robert P. Burriss

[Attractiveness](#); [Concealed ovulation](#); [Fertility](#)

Definition

Women's mating psychology, behavior, and attractiveness shift over their menstrual cycle.

Men may have evolved strategies to mitigate any undesirable effects of these shifts on their own fitness.

Introduction

Human female fertility varies over the menstrual cycle. The likelihood that a single act of intercourse will result in conception is greatest in the days preceding ovulation. At this time, women are more attractive and are more driven to enhance their attractiveness. Androphilic women become more interested in men who are not their primary partner, and their preference for physically and behaviorally feminine men decreases. Because men who are women's primary partners risk desertion or (if their partner engages in short-term sexual relationships with other men) investing in biologically unrelated offspring, they have likely experienced selection pressure to deploy counterstrategies that mitigate the effects of female menstrual cycle shifts. These counterstrategies may include changes to a man's sexual desire, his jealousy and mate-guarding behavior, and his propensity to compete with sexual rivals.

Sexual Interest

Men may respond to female shifts in sexual behavior or appearance by increasing sexual interest in primary partners who are in the fertile cycle phase. Cerda-Molina et al. (2013) collected female underarm and vulvar odor samples while the women were in the periovulatory (fertile) and luteal (non fertile) phases of their cycle. Men sniffed the samples and completed a questionnaire on their interest in sex. Men's sex interest increased after they smelled periovulatory samples but did not change after they smelled luteal samples. Other studies indicate that exposure to the body odor of women in the fertile phase results in men estimating women's sexual arousal as higher and that men are more prone to behaviorally mimic a woman in the fertile phase (Miller and Maner 2011). Increased desire and an overestimation of women's sexual interest may cause

men to more readily and more frequently initiate sex, thereby reducing the primary partner's interest in extrapair copulations, limiting her opportunities for extrapair copulations, or instigating sperm competition with her extrapair sexual partners.

Miller and Maner (2010) hypothesized that men's responses to cues of fertility in non-primary partners should vary depending on whether the man is in a current relationship. They showed that single men are more attracted to fertile than non-fertile women but that partnered men are less attracted to fertile women. Devaluing a fertile non-partner may reduce men's temptation to stray from their primary partner and promote relationship stability.

Jealousy and Mate Retention Behavior

Because men stand to lose more if their female partner copulates with other men during her fertile rather than her non-fertile phase, men may be expected to feel greater sexual jealousy and to behave in ways that minimize the likelihood of a partner straying or being poached when that partner is most fertile. Gangestad et al. (2002) had women rate the extent to which their male primary partner performed each of 41 mate retention behaviors. They found that women reported that their partner performed more of such behaviors when they were fertile, and behaviors were more frequent the nearer women were to ovulation. Proximity to ovulation was related to men's proprietariness and attentiveness, but the strongest relationship was with vigilance (checking up on the partner's location and activities). Less attractive women report that their partner is more jealous and possessive near ovulation, whereas more attractive women report consistently high jealousy and possessiveness throughout the cycle (Haselton and Gangestad 2006). Mate retention behavior also encompasses tactics that are perceived positively, and women whose primary male partner is lower in sexual attractiveness report that their partner more frequently expresses love and commitment during the high rather than the low fertility cycle phase (Pillsworth and Haselton 2006).

The Challenge Hypothesis

The challenge hypothesis posits that men may compete more strongly with male sexual rivals when in the presence of fertile females. Testosterone is implicated in sex drive and competitiveness, and research suggests that salivary testosterone levels increase in men exposed to the body odor of fertile women and decrease after exposure to the body odor of women in the non-fertile phase (Cerdeña-Molina et al. 2013). Similarly, the testosterone levels of men whose primary partners are in the fertile phase of their cycle increase after men view photographs and descriptions of rivals but only if those rivals are competitive and attractive: men whose partners were in the non-fertile phase, or who viewed uncompetitive rivals, did not experience an increase in testosterone (Fales et al. 2014).

Men may have benefited historically by an increased sensitivity to rivals at times when the threat of partner infidelity was greatest. Women are more attracted to men with masculine and dominant traits during the fertile phase of their cycle. Men whose primary partners are in the fertile phase rate male faces as more dominant than men whose partners are in the non-fertile phase but only if those faces appear especially dominant: men do not rate submissive faces differently as a function of their partner's cycle phase (Burriss and Little 2006). This shift in perception may aid men in identifying rivals who present the greatest threat to their relationship.

Conclusion

Women can only accrue the putative genetic benefits of copulating with extrapair men if copulation occurs when fertility is most likely, in the days preceding ovulation. Because women's extrapair sexual behavior is detrimental to the fitness of their male primary partner, it is plausible that men would have evolved counterstrategies to prevent their partner straying or being poached. Research suggests that men are more sexually interested in fertile women, are more apt to be jealous of fertile partners, and respond hormonally and behaviorally toward threatening rivals when

their partner is fertile. If a cost to men of deploying these counterstrategies is the increased likelihood of a partner's desertion, it would be maladaptive to do so uniformly across the partner's cycle.

A limitation of much of the research on this topic is that it relies upon women's reports of men's behavior. It is possible that, just as women's mating psychology shifts over the cycle, so too does their perception of their partner's counterstrategies. Certainly, women resist male mate-guarding more strongly when fertile (Gangestad et al. 2014). Their reports of partner mate retention behavior may, therefore, not be accurate. Also, most research on responses to women's cyclic shifts is laboratory-based and tests unrelated individuals. There is a need for more research on how men respond to cyclic shifts and on how their female partners resist counterstrategies, in real relationships (Haselton and Gildersleeve 2015).

Male Detection of Deception

T. Joel Wade¹, Kelsey Salerno¹ and James B. Moran^{1,2}

¹Department of Psychology, Bucknell University, Lewisburg, PA, USA

²Tulane University, New Orleans, LA, USA

Men and women have differing parental investment needs with respect to relationships (Trivers 1972) and place emphasis on different

characteristics when evaluating potential partners. So, not surprisingly, when it comes to mating, both sexes engage in a type of contest, so to speak, where deception occurs on the part of both sexes (Grammer et al. 2000) and both sexes expect the opposite sex to deceive and lie in order to gain a mate (Keenan et al. 1997; Benz et al. 2005). But, both men and women report being upset when they are deceived and lied to (Haselton et al. 2005), and men assume women are being deceiving the majority of the time (Goetz and Causey 2009).

The deception that occurs often centers around characteristics that are preferred by the opposite sex in order to facilitate one's outcome in intersexual competition (Benz et al. 2005; Keenan et al. 1997). The opposite sex's ability to detect deception on the part of a partner would also help them compete intersexually. But, there is an “arms race” between female deceptive skill and male detection of deception skill. Men have evolved abilities that help them detect when women are being deceitful. However, since women's deceptive abilities are also evolving, men are not always successful at detecting deception.

Men place an emphasis on women's attractiveness when they are evaluating partners (Buss 1989, 2006). Not surprisingly, women tend to deceive men by altering their physical attributes, specifically by engaging in self-enhancing behaviors (Tooke and Camire 1991). But, men tend to fail at detecting changes in women's physical appearance, and the research indicates that men's detection of deception tends to be no better than chance (Klaver et al. 2009). A real-life example of a man's failure to detect physical appearance changes on the part of a woman involves the case of a man who sued his wife after discovering her plastic surgery (Li 2013).

One way men could be able to detect physical appearance deception on the part of a woman would be via pheromones. Women are most fertile and most reproductively fit when they are ovulating, and artificial pheromones do not increase attractiveness (Grammer et al. 2005). Thus, even though a woman may alter her appearance to appear more beautiful, a man would still be able to determine if he is being

deceived by focusing on the pheromone profile the woman is emitting.

Another area where women may seek to deceive a man is regarding being sexually unfaithful. Women may engage in this deception because a man's reaction to a female partner's sexual infidelity may involve physical violence against the woman (Daly et al. 1982). If a man fails to detect sexual infidelity on his female partner's part, he runs the risk of being cuckolded into investing in another man's offspring, wasting his resources, and thus reducing his fitness and genetic legacy. Research shows that men are indeed best at detecting sexual infidelity, rather than emotional infidelity on a partner's part (Shackelford and Buss 1997). Men focus on cues such as "increased reference to and time spent with another person"; "passive rejection of partner/inconsiderateness"; "acting guilty and being anxious toward a partner"; "angry, critical, and argumentative toward a partner"; "emotional disengagement from a partner"; reluctance to spend time with a partner"; reluctance to discuss a certain person"; and relationship and dissatisfaction/loss of love for a partner" to detect infidelity on a female partner's part. These points suggest men have developed adaptations to help them detect deception on the part of women.

Male Dominance Hierarchies

Romain Ligneul
Champalimaud Neuroscience Program,
Lisbon, Portugal

Dominance *relationships* refer to asymmetries of control within dyads of individuals. Whether this control is exerted over nutritional resources, space, or sexual partners does not fundamentally matter, as long as framing social interactions in terms of dominance enables the observer to better

predict the outcome of these interactions (Bernstein 1981). For example, the concept of dominance can be invoked when predicting that if A has won over B in the past, then A will also win over B in the future or that if A prevails over B when competing for food, then A will also prevail over B when competing for space or sexual partners.

By contrast, dominance *hierarchies* refer to the transitive manifestation of the aforementioned asymmetries within a social group, such that if one has observed that A dominates B and B dominates C, then one can deduce that A will dominate C. This transitivity criterion plays a key normative role in determining which behavioral metrics are suitable for the assessment of dominance hierarchies. The most famous of these metrics is perhaps the “pecking order” early described in chicken by Schjelderup-Ebbe (1921), where ranks are defined based on priority access to nutritional resources. Yet male dominance hierarchies are now mainly defined on the basis of directional aggression patterns. Although many other transitive metrics can result in stable estimates of hierarchical structures (approach-retreat, facial displays, vocalizations, etc.), aggression is indeed easy to observe and generalizes well across species.

Hierarchical gradients have multiple consequences for the physiology of male individuals which are most often mediated by the influence of steroid hormones and, to a lesser extent, by inflammatory and immune pathways. Individuals of lower ranks have typically higher circulating levels of cortisol, resulting from repeated exposure to social stressors and forewarning fitness-reducing outcomes like hypertension or diabetes (Sapolsky 2004). In some species, these physiological counterparts are so profound that behavioral assays become superfluous to infer dominance. For example, in the African cichlid fish, dominant and subordinate individuals can be readily distinguished on the basis of a specific pigmentation pattern around the eyes (Burmeister et al. 2005). Closer to us, subordinate orangutans retain salient juvenile traits for many years (i.e., lack of cheek flanges, reduced weight, etc.) until the alpha male finally loses dominion

(Pradhan et al. 2012). But it is perhaps in male anole lizards that the most spectacular effects of dominance are observed, as a single social defeat can turn body color from bright green to brown in 1 hour (Greenberg and Crews 1990). Because changes are mostly triggered in subordinate individuals following social defeats and other unfavorable competitive outcomes, some authors have suggested that the term “subordination hierarchy” would better reflect the biological bases of social ranks (Rowell 1974). This shift of perspective is crucial because many of these changes represent more than mere correlates of social rank: instead, they tend to reinforce hierarchical structures themselves by weakening further the competitive abilities of previously defeated individuals – a widespread phenomenon known as the “loser effect” (Rutte et al. 2006).

From an evolutionary viewpoint, the most relevant observation is certainly that subordinate individuals tend to reproduce less efficiently than dominant ones in most taxa, including primates (Ellis and Lee 1995). Although rarely complete, likely exacerbated by captivity and more prevalent in females, this reduction of reproductive success indicates that dominance hierarchies partly mediate the process of natural selection. For example, in chimpanzees, the alpha male routinely sires between one- and two-third of the offsprings (Newton-Fisher et al. 2009). This common observation depends on several causes whose respective contributions vary from one species to another: (i) active guarding of fertile females by dominant males, (ii) delayed acquisition of secondary sexual characteristics in subordinate males due to inhibition of androgen release, and (iii) mating choices of females revealing a preference for dominant males. Complementing prestige- and wealth-dependent mating, this latter effect is significant in humans where it is further gated by women hormonal status (Havlicek et al. 2005; Roney and Simmons 2008). In turn, since dominance hierarchies have exerted a long-lasting pressure in the course of evolution, numerous subordinate traits can be conceived as adaptations selected to minimize the threat to reproductive fitness associated with unfavorable social contexts. In the field of “Darwinian psychiatry”

(Price 1967), the core symptoms of prevalent mental disorders are thus largely envisioned as the downside of mechanisms which used to be adaptive in prehistoric societies before becoming dysfunctional in modern societies. For example, the drive to withdraw which accompanies depression might represent an adaptive response to social defeat, as it can reduce the risk of harm and might even facilitate access to reproductive partners beyond the attentional focus of mate-guarding dominant males.

Finally, it must be emphasized that the manifold consequences of dominance hierarchies depend heavily on the neurocognitive processes which underlie the perception of control over events (Qu et al. 2017). Indeed, it is well known that the lack of control over stressful events dramatically exacerbates their detrimental consequences over physiology and behavior, even when the objective amount of stress is kept equal (Maier and Seligman 2016). Presumably mediated by neuromodulatory systems such as serotonin – which has also been involved in aggression and dominance from lobster to humans (Edwards and Kravitz 1997; Duke et al. 2013) – this overarching impact of control brings us back to the very definition of social dominance. Moreover, because these neuromodulatory systems are highly plastic, because they influence a wide array of brain functions, and because they are ubiquitous in the animal kingdom, they provide a unique window on the interplay of dominance and evolution. Understanding how the evolutionary dynamics has sculpted these systems so as to adapt individuals to the hierarchical social structure surrounding them may eventually help us to understand the origins and the mechanisms underlying the so-called socioeconomic health gradient, which explains why millions of human beings are literally sick of male dominance hierarchies (Adler et al. 1994).

Male Friendship

Gareth Craze

Case Western Reserve University, Cleveland, OH, USA

Synonyms

Bromance; Fraternal relationality; Fraternity; Male bonding

Definition

Friendly relationships between related or unrelated males.

The developmental rationale underpinning friendship is well-substantiated in the literature. The process of developing and maintaining friendly bonds with kith is crucial for human children to develop Theory of Mind, interpersonal reasoning, and their faculties for moral judgment. Friendships also serve as a form of social training ground; one in which our earliest instances of developing empathy, forming coalitions, and resolving conflicts begins to take root.

Male-male friendship – what has often colloquially come to be referred to as male bonding or “bromance” (Tiger 2017) – possesses unique dimensions from both an evolutionary and a developmental perspective. From early childhood, male-male friendships are characteristically defined by a greater frequency of rough-and-tumble play, rehearsed belligerence, participation in games governed by systems thinking and strictly codified rules, and the establishment of clearly-defined hierarchies and role positioning. This is in stark opposition to typical female-female friendships during childhood, which tend toward egalitarianism, inclusiveness, and games based more on participation and fair play than rules and rewards (Bjorklund and Pellegrini 2000).

Throughout adolescence and into adulthood, male-male friendship often reflects many of its

early developmental antecedents. Male friendships – consistent with male psychology generally – tend to be more “things-oriented” than “people-oriented”; driven more by mutual interests and activities than by the deeply affectionate personal bonding that is more characteristic of female-female friendships (Robinson et al. 2017). That said, there is a unique affective dimension to male-male friendships that complements the more utilitarian and systemic qualities that are generally more apparent in such friendships. Indeed, one study noted that an overwhelming majority of males preferred to share deeply emotional insights and highly personal matters with their male friends than with their female romantic partners. The authors observed that, for most of the men surveyed in their study, “bromantic relationships were more satisfying in their emotional intimacy, compared to their heterosexual romances” (Benenson et al. 2014).

It seems likely that the capacity for developing and maintaining friendships along same-sex lines generally, and in male-male friendships specifically, had significant adaptive value for the evolution of our species. In ancestral times, males were responsible for the greater preponderance of game hunting; sorties which may have lasted days or weeks depending on the local climate and season, as well as the predatory or grazing patterns of the fauna being pursued (Hildebrandt and McGuire 2002). Such hunting activity would have unquestionably been highly labor-intensive and physically draining, and would also have required significant intra-party co-ordination, division of labor, and collective buy-in as to the relative distribution of the eventual spoils. Time spent away from camp, and thus romantic partners and children, would have likely exacted an additional mental and emotional toll on the participants (Lewis et al. 2011).

Male-male friendship, thus, likely has deep evolutionary roots in humans. The ability to form close bonds with one’s same-sex peers would have allowed males to participate in hunting activity in a harmonious, collectively cohesive manner in spite of the substantial emotional pressure that

accompanied such an emotionally taxing and threat-laden pursuit. It would likely have provided an additional layer of mental reassurance through interpersonal concord, clearly explicated roles and responsibilities, and a unified focus on the particularities of the task at hand. The cognitive and behavioral features of male-male friendship in antiquity likely parallel those found in the “bromantic” relationships of their modern analogues.

[Men romantic partner choice](#); [Men sexual partner selection](#)

Definition

Romantic or sexual partner selection by men; characteristics that guide male choice of their romantic or sexual partners.

Introduction

According to the Parental Investment Theory (Trivers 1972), males and females present their mating strategies related to the investment they make in their offspring. In general, females tend to invest more time and energy in their children. Males, on the other hand, do not invest in offspring as much as females do, and the low paternal investment necessity allows them to invest more time and energy in mating effort. For them, engaging more in short-term relationships, with different sexual partners, increases their probability of having a greater reproductive success since they can have more children in a short period of time. Therefore,

men's reproductive success is limited by their access to women, which leads them to compete to have access to females, a limiting resource.

Sexual Strategies Theory

Observing men and women romantic partners preferences, Buss and Schmitt (1993) noticed both sexes focus on different characteristics. Distinct evolutionary pressures have acted on men and women and have led them to valorize different traits in their partners in order to maximize their reproductive success.

Because of women's high physiological investment in children (9 months of gestation, breastfeeding, and the primary care with children), men tend to prioritize physical attractiveness more than women do (Buss 1989).

Physical Attractiveness

As the physiological investment by women is mandatory, men who choose their partners based on characteristics that give them cues about women's good physiology for having children, such as ideal estrogen levels, have increased their reproductive success (Karremans et al. 2010). Karremans et al. (2010) found that women's body in hourglass shape (waist-to-hip ratio of 0.7) is considered more attractive. This proportion of fat distribution is positively associated with the neural development of the embryo, and women who have ideal estrogen levels accumulate more fat in the hip area.

Age

In addition, due to the relation of women's physiology and fertility, another important trait is age (Kenrick and Keefe 1992). Women have a short period during which they can reproduce when comparing to men. Women start being reproductive with menarche, having their reproductive peak around age 24 and stop reproducing at menopause (around 50 years old). With the increase of men's

age, there is a decrease of their fertility because of sperm quality (such as ill-formed sperm) and quantity, but there is no interruption of their reproduction (Pawlowski 2000). Thus, age is a limiting factor of female reproduction and, therefore, important when men are looking for a partner.

Strategy Change

Even though men tend to adopt a short-term relationship, there are some circumstances that might lead them to modify their strategy from short- to long-term. One factor that can influence men's strategy change is the percentage variation of women in a population. A men-biased operational sex ratio forces men to choose a partner and commit to her faster than usual in order to guarantee at least one woman by his side, since some men will not have access to her (Kruger et al. 2010).

Another factor that might influence men's strategy is their perception of social acceptance. Men who perceive themselves as less accepted socially tend to decrease their self-esteem and, consequently, their mate value evaluation (Penke and Denissen 2008). Men with a low self-esteem level, as men in a men-biased population, also tend to commit faster than usual.

Conclusion

In order to maximize their reproductive success, men tend to invest more in short-term relationships, for having the possibility of getting greater access to women. Women invest more physiologically in children when compared to men. This factor leads men to search for characteristics that signal women's capacity to have children. Through physical attractiveness, men assess information about women's youth and fertility, important factors to women's reproductive potential.

Definition

Sexual selection has shaped the evolution of extravagant secondary sexual characters in males via female choice (intersexual selection) and male-male competition (intra-sexual selection). Visually conspicuous sexually dimorphic characters can play a purely ornamental role in sociosexual interactions as “badges of status” communicating maturity, social status, dominance, and sexual attractiveness. This entry takes a Darwinian comparative approach spanning monkeys, apes, and man to outline how sexual selection has shaped male ornamentation.

Introduction

Sexual selection theory asserts that female choice, male-male competition, or their combination has shaped the evolution of sexually dimorphic male secondary sexual characters (Darwin 1871). Ornaments embellish and elaborate upon underlying bodily or facial structures and, in some cases, are part of coordinated behavioral displays that serve to attract females (Puts 2010). In other cases, ornaments function as badges of status, enhancing aspects of male sexual maturity, social rank, and dominance during male-male social encounters (Puts 2010). This entry takes a Darwinian comparative approach spanning monkeys, apes, and man to outline how sexual selection has shaped male ornamentation.

Sexual Dimorphism in Male Ornamentation Among Anthropoid Primates

In *The Descent of Man, and Selection in Relation to Sex*, Darwin noted the pronounced sexual dimorphism in visually conspicuous ornamentation, canine size, and body mass among anthropoid primates and suggested sexual selection had shaped their evolution (Darwin 1871). Particular attention was given to the role of male ornamentation in communicating social rank, status, and dominance that, in turn, may be associated with male attractiveness and reproductive success. Some striking examples of visually conspicuous male ornaments are shown in Fig. 1, which show the red facial coloration of male mandrill (*Mandrillus sphinx*), the white and gray capes of hair in hamadryas baboons (*Papio hamadryas*), the large nose in the male proboscis monkeys (*Nasalis larvatus*), the fleshy cheek flanges in orangutans (*Pongo* spp.), the triangular patches

of red skin on the chest of geladas (*Theropithecus gelada*), and the beardedness in men (*Homo sapiens*; Dixon et al. 2005). The sections that follow discuss the role of mating systems, social group sizes, and social group organizations may have had on shaping ornamentation among male primates.

Sexual Selection, Mating Systems, and Male Badges of Status

The largest sex differences in body mass and canine size occur in primate species with polygynous mating systems, followed by multi-male multi-female mating systems, with monogamous mating systems being the least sexually dimorphic (Dixon et al. 2005). Polygynous systems are characterized by stronger intra-sexual selection for access to females, maintaining harems and protecting females and infants than multi-male multi-female or monogamous mating systems

Male Ornamentation, Fig. 1 Some of the most striking examples of sexually dimorphic ornaments in male anthropoids. The top row shows from left to right the red uakari (*Cacajao calvus*), man (*Homo sapiens*), and golden snub-nosed monkey (*Rhinopithecus roxellana*). Pictures on the

bottom row from left to right show the Bornean orangutan (*Pongo pygmaeus*), mandrill (*Mandrillus sphinx*), and proboscis monkey (*Nasalis larvatus*). (The drawings are used with permission from Alan F. Dixon)

(Dixson et al. 2005). Thus, augmented body size and canine size may play an important role in intra-sexual competition among male nonhuman primates with polygynous mating systems compared to species with other mating systems (Dixson et al. 2005).

Ornamentation in male nonhuman primates may not be biologically homologous to those in men. However, they may play analogous roles as sociosexual signals (Dixson et al. 2005). If these ornaments were sexually selected by female choice, male-male competition, or some combination of the two processes, one would predict that their expression would vary due to the mating system. Quantitative analyses of sexual dimorphism in male primate ornamentation, including all hairy, fleshy, and colorful characters, revealed ornaments were more developed among species with polygynous than monogamous or multi-male/multi-female mating systems (Dixson et al. 2005). Those analyses included men's beardedness, body hair, and patterned baldness. While humans are primarily serially monogamous, in some cultures high status males may be polygynous (Puts 2010). Irrespective of whether men were included in the analyses as monogamous or polygynous, polygynous primates scored highest for ornamentation followed by species with monogamous mating systems, with species with multi-male multi-female mating systems scoring the lowest (Dixson et al. 2005). When men were included as a monogamous species, monogamous primates had higher ornamentation scores than multi-male multi-female species. When men were included as a polygynous species, the differences between monogamous and multi-male multi-female species were no longer significant, and the effects of polygyny on ornamentation was strengthened. Thus, men are similar to species of male nonhuman primates with some degree of polygyny in the mating systems.

Social Group Sizes, Social Organizations, and Male Ornaments

In addition to mating systems, the social environment profoundly affects the strength of mate competition. The complexity of male facial

coloration is positively correlated with social group size in Old World monkeys and apes (*Catarrhini*; Santana et al. 2013). In New World monkeys (*Platyrrhini*), color patterns have evolved to facilitate individual recognition in smaller social groups (Santana et al. 2013). Facial color complexity varies with sympatry among Old and New World primates, so that more gregarious and sympatric species have more complex facial coloration than less gregarious and non-sympatric species (Santana et al. 2013). To further explore how social and ecological factors relate to the expression of ornamentation in male monkeys, apes, and men, Grueter et al. (2015) used a refined classification of primate social organization and social group size as predictors in phylogenetic comparisons of sexual dimorphism in ornaments. Results revealed a positive relationship between ornamental dimorphism and group size, which remained after controlling for other independent variables such as habitat type and fission-fusion dynamics. Ornamental dimorphism also differed according to social organization, being greatest in males from species with multilevel social organizations. Thus, men were similar to species of nonhuman primates with large social groups and multilevel social systems wherein males have well-developed visually conspicuous sexually dimorphic traits. These findings suggest that in complex social systems characterized by larger social groups, individual recognition may be compromised and the need to signal rank, dominance, or attractiveness may be greater.

Sexual Selection and Men's Beardedness as an Ornamental Badge of Status

Comparative studies of ornamentation among male anthropoid primates suggest that men's ornamentation reflects sexual selection via male-male competition and female choice (Dixson et al. 2005; Grueter et al. 2015). Beards represent possibly the most strikingly sexually dimorphic ornament between men and women. Sex differences in facial hair emerge during adolescence under the dual actions of testosterone and dihydrotestosterone (DHT), where facial

hair follicles require the conversion of testosterone to DHT via the actions of the enzyme 5 alpha reductase 2 for their activation and growth (Dixon et al. 2016). Dixon and Vasey (2012) showed using images of men with their natural amount of beard growth at 4–8 weeks that bearded faces were judged as more socially dominant and aggressive by men, but less attractive by women, than clean-shaven faces (Fig. 2). This suggests beards play a stronger role in intra-sexual communication between males than enhancing attractiveness to women.

The ease with which men can groom and remove their facial hair suggests that variation in men's beardedness may not communicate underlying genetic quality (Dixon et al. 2016). Indeed, there is little evidence that women's preferences for men's beards are stronger under contexts favoring short-term mating strategies (for review, see Dixon et al. 2018). Instead, cross-cultural research has shown that women's preferences for full beards are stronger in countries with low-average incomes and more male-biased sex ratios and in larger cities where men

tend to be more bearded and life expectancy is higher (Dixon et al. 2017, 2019b). As facial hair communicates aspects of male age, sexual maturity, and social aspects of dominance and status (Dixon and Vasey 2012; Craig et al. 2019), beardedness is preferred under conditions where women may benefit from an intra-sexually competitive partner (Dixon et al. 2017, 2019b). Interestingly, women state stronger preferences for beards when judging male stimuli for long-term relationships and paternal investment where tangible resources that directly benefit the survival of mothers and their children may be acquired (reviewed in Dixon et al. 2019a). Studies comparing ratings of beardedness and clean-shaven male faces suggest that beards enhance perceptions of age, masculinity, dominance and parenting abilities among mothers compared with non-mothers (reviewed in Dixon et al. 2019a). Taken together, men's beards may represent a classic example of a Darwinian ornamental badge of status that enhances men's age, social status, and attractiveness when considering long-term rather than short-term mating contexts.

M

Male Ornamentation, Fig. 2 These data show mean ($\pm$ 1 SD) ratings of clean-shaven (Open bars) and full bearded (gray bars) faces made by women and men from New Zealand. A total of 129 women rated stimuli posing smiles for attractiveness (a); a total of 52 men rated faces

posing neutral expressions for social dominance (b); a total of 111 men rated faces posing angry expressions for aggressiveness (c). (This figure is reproduced using data from Dixon and Vasey (2012) and the stimuli are owned by Barnaby Dixon)

Conclusion

Over 150 years ago, Darwin suggested that visually conspicuous sexually dimorphic ornamentation in male primates functions as badges of status during male-male competition that, in turn, influence female mate choice. For many years these hypotheses, particularly as they apply to the evolution of masculine characters in men, remained largely unexplored. A resurgence of interest in how men's ornaments function in sociosexual communication highlights a key role of male-male competition in shaping men's mating success. Future research exploring how the strength of intra-sexual selection on male ornaments relates to men's mating success under variable ecological, social, and economic factors will be valuable.

Synonyms

[Hormonal cues to attractiveness](#); [Male preferences](#); [Menstrual cycle changes](#)

Definitions

Men tend to perceive female appearance and behavior as slightly more attractive during the follicular phase of their cycle.

Introduction

Women lack the conspicuous morphological and behavioral changes related to their menstrual cycle that are seen during estrus in some old-world monkeys, such as baboons, or in some apes, such as chimpanzees. In these species, changes in morphology and behavior – including genital swelling and active sexual solicitation – tend to peak in the fertile phase of the cycle and elicit elevated interest and sexual activity in their male conspecifics. Although they are not as conspicuous, some cyclic fluctuations in physical appearance and behavior can nonetheless be observed in women.

Cyclic Change in Women's Appearance

Studies of cyclic fluctuations in attractiveness have focused on perception of individual attributes such as faces, body odor, and voice. Several studies have shown that facial images taken during the follicular phase are rated as more attractive when compared to images taken during the luteal phase of the cycle (e.g., Roberts et al. 2004). Attractiveness changes are associated with changes in skin color, skin texture, and facial shape, occurring perhaps due to cyclic fluctuation in fluid retention.

Similarly, axillary and vaginal odor is perceived to be most attractive during the follicular phase, and fluctuations are absent or attenuated in women using hormonal contraception (Kuukasjarvi et al. 2004). Exposure to female body odor collected during the fertile phase may elevate testosterone levels in men, although other studies did not confirm this effect (Roney and Simmons 2012). While the chemical compounds responsible for the aforementioned fluctuations in perception of female body odor are not yet fully characterized, they may include fluctuations in concentrations of short fatty acids.

Vocal attractiveness follows a similar pattern as observed in the perception of faces and body odor. Again, we also know something about the proximate mechanisms involved: the increase in perceived vocal attractiveness is at least partly related to elevated voice pitch during the follicular phase (Fischer et al. 2011).

Cyclic Changes in Behavior

Cyclic fluctuations in attractiveness are not restricted to physical cues; they can also be observed in various behavioral cues. For instance, it has been shown that women at mid-cycle prefer to dress in clothes that reveal more skin and are more likely to wear red and pink colors (Haselton et al. 2007), which are associated with higher attractiveness judgements. Women in the fertile phase also tend to use more cosmetic products. Cyclic fluctuations have also been observed in the perceived sexiness of dance (Fink et al. 2012) and gait, although in the latter case, the reported pattern varies across individual studies – some studies reported a peak during the follicular phase (Fink et al. 2012), while another study found the same peak during the luteal phase.

In contrast to available evidence gathered under controlled conditions, our understanding of how such cyclic effects are perceived in real life is rather limited. So far, only one study aimed to assess whether changes in appearance and/or behavior might have some real-life consequences. In a sample of lap dancers, women earned significantly more in tips during the fertile phase than other parts of the cycle, but again, no similar pattern was found in hormonal contraceptive users (Miller et al. 2007).

Menstrual cycle also appears to affect perceptions of coupled men toward their female partners. Similar to the studies reviewed above, all of which focused on cyclic fluctuations in perceived attractiveness of unfamiliar women, men perceive their partners as more attractive during the fertile window, but such fluctuations are not evident in men whose partners were using hormonal contraceptives. Furthermore, women report their partners as being more possessive and attentive during their fertile phase (Thornhill and Gangestad 2008).

Methodological Considerations

Most studies interpret higher attractiveness judgements in the follicular phase as detection of ovulation. However, this is somewhat misleading as ovulation itself is a relatively short, internal

physiological process which can be detected only by hormonal assays or ultrasonography. Furthermore, many of the published studies did not confirm whether an actual ovulation occurred using luteinizing hormone assays. This is an important issue as a not insignificant proportion of cycles in healthy women appear to be anovulatory – conservative estimates place this between 8 and 12% – although the actual proportion may vary extensively depending, for instance, on women's age, physical activity, and nutritional status. Furthermore, due to significant variation in cycle length and thus also in timing of the fertile window, counting methods only crudely estimate actual fertility. Together with small effect sizes, this might be a reason why cross-sectional studies often fail to find cyclic effects. To avoid these shortcomings, rigorous guidelines on methodology of menstrual cycle-related studies were recently provided and include, for instance, the use of within-subject design and employment of hormonal assays to better estimate the conception probability (Gangestad et al. 2016). Another methodological issue concerns stimulus presentation. Stimuli collected in different phases of the cycle are subsequently presented simultaneously. In principle, this never happens in real life and may thus overestimate actual effect sizes.

Evolutionary Interpretations

In general, effect sizes of the reviewed cyclic effects tend to vary from small to modest, and their evolutionary significance is currently hotly debated. The mainstream view tends to interpret male sensitivity to observable cyclic cues as an adaptation (Thornhill and Gangestad 2008). According to this view, men more sensitive to such cues might increase their chances for conceptive sex and thus increase their fitness. Similarly, coupled men sensitive to cyclic cues in their partners may increase mate guarding to reduce the chances of their partners' infidelity. However, the predictive value of such changes appears to be relatively low. For instance, Fischer et al. (2011) note that the overall variation over the cycle precluded the unequivocal identification of ovulation. Also, there are currently no studies

testing cross-modal integrations of the observed cycle-related effects.

Alternatively, behavioral and perceptual sensitivity to fertile phase cues may be by-products of an adaptation to discriminate ovulatory from anovulatory cycles or indeed as a by-product of more general preferences for women with high potential fertility (i.e., the overall likelihood of being able to conceive) (Havlíček et al. 2015). Male preferences for cues of potential fertility, such as estrogen-related facial cues or low waist-to-hip ratio, have higher effect sizes compared to those for within-cycle changes and are generally considered to be an adaptation. Both within-cycle fluctuations in attractiveness and between-individual differences in attractiveness appear to be based on a shared underlying hormonal mechanism (e.g., levels of estrogen and progesterone). It could therefore be possible that the former arose as an inevitable perceptual by-product (or spandrel) of the latter. This is supported by considerably higher between-individual variation as compared with within-individual cyclic changes. Thus, in future studies, there is a need for more focus on the comparison of cycle-related within-women fluctuations and between-individual differences, in conjunction with measurement of levels of circulating sex hormones.

Conclusions

Changes in menstrual cycle-related attractiveness have been observed in various modalities including facial appearance, body odor, voice, and some behaviors such as gait and appearance enhancements. These fluctuations tend to be absent in women using hormonal contraception, indicating involvement of sex hormones, although exact mechanisms are currently not well understood. Nevertheless, the effect sizes of the cyclic changes are typically small to moderate. Cycle-related changes in attractiveness are often interpreted as men's adaptation to cues of current fertility which may increase probability of conception. Alternatively, perception of cyclic fluctuations in attractiveness may be a by-product of more general preferences for women with high potential fertility, as both within-individual cyclic changes and

interindividual differences are based on a shared underlying hormonal mechanism.

Definition

The act through which males protect themselves and/or others.

Introduction

Natural selection favors those physical and psychological traits that are beneficial in terms of reproduction and survival (Dobzhansky 1956). Human ancestral times were characterized by prevalent violence, consisting both of within and between group conflict (Duntley and Shackelford 2012; LeBlanc 2003; Puts 2010). As a result, both men's and women's psychology could have been influenced by such violent contexts, leading to preferences for certain physical traits related to protection from partners or allies (men's: Borráz-León et al. 2014; women's: Buss 1994).

Male Protection for Females

On average, women are shorter, smaller in size, less aggressive, and have a weaker body composition compared to men (Daly and Wilson 1988). Evidence from archeological archives suggests that damage of property, homicide, and rape were common practices during human evolutionary history (Keeley 1996; LeBlanc 2003). During this time, conflict was mostly driven by intra-sexual competition between men (Archer and Benson 2008; Little et al. 2013; Puts 2010), hence women's physique could have made them more vulnerable to becoming victims of crime and violence elicited by men (Duntley and Shackelford 2012; Perilloux et al. 2012). The costs associated with men's aggression against women ranged from physical and psychological pain (Thornhill and Palmer 2000) to death (Duntley and Shackelford 2012). In order to minimize or avoid these costs, women are thought to have evolved psychological strategies to protect themselves from potentially being hurt (Duntley and Shackelford 2012).

Women's preferences may have thus shifted toward men with the ability to protect them from violence and therefore decrease victimization risks (Li et al. 2014). Previous studies have suggested that traits that indicate men's protective capabilities, their probability to survive in agonistic encounters, and deter competitors could be their physical formidability, aggressiveness, and

coerciveness (Snyder et al. 2008). Findings on who women prefer as partners have supported this idea. Buss (1994) found that women choosing potential partners had a higher preference for men who could offer protection for themselves and their children. Likewise, Snyder et al. (2011) found that when women felt at higher risk of crime, they preferred partners who looked more formidable and dominant. Taking this idea further, Ryder et al. (2016) found that women's preferences for more formidable and dominant men were exacerbated in crime hotspots and decreased in safespots. Furthermore, women have been found to prefer friends, short-term mates, and extra-pair partners who were described as protective (Bleske-Rechek and Buss 2001; Greiling and Buss 2000). These results suggest that women prefer to be in contact with men (either as partners or friends) who are more capable of protecting them under violent contexts.

Women's higher preferences for more formidable partners are not restricted to bodily features; it extends to facial ones too. For example, men's facial masculinity, which has been directly related to perceptions of dominance (Fink et al. 2007; Little et al. 2013), was preferred by women who were primed with images of male on male conflict (Li et al. 2014). Findings from Li et al. (2014) suggest that when women face danger they prefer partners who would be more able to protect them as well as partners who are more masculine, formidable, and dominant (Windhager et al. 2011).

Men's ability and willingness to protect women can be considered both an asset and a liability. A protective partner would be characterized by being more aggressive, dominant, and physically formidable (Snyder et al. 2011). Although a partner with these traits may seem advantageous in a violent scenario, it could be dangerous as well (Borrás-Guevara et al. 2017a; Li et al. 2014; Snyder et al. 2011). For instance, men's aggressiveness correlated positively with coercion and predicted partner abuse (Lorber and O'Leary 2004). Furthermore, aggression, coerciveness, and getting more involved in fights are more common between stronger than average men (Archer and Thanzami 2009; Sell et al. 2009). While there is a clear association between

men's protective traits and women's risk of being hurt, most research on the influence of violence on women's mate preferences has focused on the benefits women obtain when choosing a protective partner. Only a few studies have done research on the potential costs that women would face as well when preferring such kind of partners (Borras-Guevara et al. 2017a; Li et al. 2014; Snyder et al. 2011). Li et al. (2014) found that when women were primed with images of men punching women, their masculinity preferences dropped. More recently, while studying a Colombian population, Borras-Guevara et al. (2017a) found that women who feared men being dangerous to their children had lower masculinity preferences for male faces.

The findings from Borras-Guevara et al. (2017a, b) and Li et al. (2014) both illustrate the multi-modalism of violence. Indeed, studies on public violence have revealed that this type of violence is mainly driven by intra-sexual competition between men (Wilson and Daly 1985). In domestic violence reports, however, women are commonly the victims and men the perpetrators (Zlotnick et al. 1998; Brewster et al. 2002). Therefore, women's partner preferences should reflect the different roles men and women play during public or domestic violence.

Due to the above, living in a violent environment may not be the only criteria women take into account when choosing a protective partner, they should also take notice of the incidence and severity of different types of violence (Borras-Guevara et al. 2017a, b). That is, choosing a protective partner may be a priority when domestic violence is perceived as infrequent, but public violence is recurrent (Borras-Guevara et al. 2017b). In fact, Colombian women's partner preferences confirm this claim. Women who were asked about their perceptions of domestic and public violence, whose perceptions of within partnership violence were higher, had lower masculinity preferences for male faces (Borras-Guevara et al. 2017b).

The existing research supports the idea that women's mating preferences reflect a need for protection; however, the type of partner they prefer may shift depending on the source of violence. If women face higher public violence,

where conflict is mainly between men, they may be better protected by more aggressive, formidable men. Yet if domestic violence is instead more common than public violence, women may be better off partnering up with someone less likely to be aggressive toward them (i.e., someone less aggressive and formidable).

Male Protection from Males

Men's psychology, like women's, may have been influenced by the high frequency of violence in ancestral environments (Borráz-León et al. 2014; Duntley and Shackelford 2012). In such contexts, men would benefit from recognizing potential allies to approach, from whom they could gain protection from, or potential rivals to avoid (Borráz-León et al. 2014). In support of this idea, Sell et al. (2009) as well as Holzleitner and Perrett (2016) found that men can accurately evaluate other men's fighting abilities by precisely identifying physical cues of strength. An additional explanation, however, is that this ability reflects men's need to protect themselves from potential cuckoldry since during human evolution, male intra-sexual competition for female partners was fierce (Puts 2010).

Previous research has found that men's preferences for other men match that of women (Batres and Perrett 2014; Borras-Guevara et al. 2017a, b; Borráz-León et al. 2014). On the one hand, these findings could support the idea that men's preferences for more formidable males reflect a need to recognize potential rivals, who would be more attractive for potential partners. On the other hand, men's preferences could reflect their ability to identify males that represent a lower/greater threat to them. Following this idea, Borras-Guevara et al. (2017a) reported that Colombian men, who feared about general violence, preferred less masculine male faces, just as women did, suggesting that when facing conflict, men would prefer male allies who represent to them a lower risk of being hurt. How much protection is gained from an ally, however, depends on the physical abilities of both parties involved. That is, a man's own physical strength influences his perceptions of potential

competitors (Fessler et al. 2014). Indeed, Watkins et al. (2010) found that when men considered themselves as less dominant than the average, they were more likely to associate facial masculinity with fighting capacity, compared to men who rated themselves as more dominant.

Men's need for protection, reflected in their preferences for allies, may depend on the source of violence too. Domestic violence is not a matter that only affects women. In fact, in the last 10 years, within-partnership violence against men in the UK has increased by 500%. To date, however, no study has focused on the effects of different types of violence on men's preferences for allies or enemies.

Conclusion

Overall, the existing literature agrees with the notion that women's mating preferences under violent circumstances reflect a need for protection. However, these preferences are contingent on the type of violence women need to protect themselves from. Studies that have taken into account women's fear of public violence, or violence between men, have found that under these conditions women prefer more formidable-aggressive men. When other types of violence were also studied, for example, domestic violence, women preferred less formidable and aggressive partners. In the case of men, it is still not clear if preferences for other males reflect either a desire to gain protection, avoid costs associated with agonistic encounters, or to discern what potential partners want. More studies on both women's and men's preferences for male protection are thus needed to clarify and reach a consensus about their causes.

[Adjustment of copulatory/ejaculatory investment;](#)
[Strategic ejaculate investment.](#)

Definition

Males do not maximally inseminate females each mating, but rather strategically inseminate sperm according to intrinsic factors such a body condition and extrinsic factors such as sperm competition risk and female quality.

Introduction

The root of the evolutionary differences between the sexes is gametic anisogamy, whereby males produce lots of tiny and relatively cheap gametes, while females produce fewer immotile and relatively more expensive gametes. Despite the relative difference in gametic investment between the sexes, males are clearly not always eager to mate, just as females are not always reluctant to mate to protect their high investment. And even when males do mate, they do not always inseminate females with the largest possible ejaculate or best quality sperm that they can make. Instead, ejaculates are often modified according to intrinsic and extrinsic factors (Wedell et al. 2002).

Ejaculatory and Copulatory Adjustment

Adjustment of copulatory investment in males has been known for decades. The Coolidge effect refers to the observation that a male placed in an arena with multiple females will mate repeatedly with all the females up to the point of apparent sexual exhaustion. However, when a new female is introduced to the group, the male will quickly recover and mate with renewed vigor with the new female (*Rattus rattus*). Males will also adjust their ejaculate investment and inseminate the new female with greater amounts of sperm (*Gallus gallus*). Such strategic investment makes evolutionary sense. Continuing to mate with the same female would likely be wasteful beyond the point at which the female has either acquired enough sperm to fertilize all of her eggs or has been sufficiently stimulated by the male to use his sperm.

Ejaculate Production Is Costly

The physiological cost of ejaculate production, including sperm and seminal fluid production, can be significant. Therefore, sperm prudence is necessary, as males can be limited in the amount and quality of sperm, as well as the amount and quality of seminal fluid they can produce during a reproductive season (Wedell et al. 2002), and males can lose fitness after repeated ejaculation due to sperm depletion. Ejaculatory investment often varies according to the male's body condition. When males are in better condition, they can have larger testes and produce higher-quality sperm than when they are in poor condition.

Extrinsic Factors Affect Ejaculate Investment Across Taxa

Ejaculate investment can be influenced by extrinsic factors affecting male mate choice and sperm competition (Kelly and Jennions 2011). Males will inseminate more sperm when they perceive sperm competition to be high (in the presence of a male that can witness copulations by a pair) than when no other rivals are present.

Males also allocate more or better quality sperm to females that will produce a higher fitness

payoff to the male investment (Kelly and Jennions 2011). Higher-quality females can include those deemed to be more fecund, unmated, more genetically compatible, and more distantly related (Kelly and Jennions 2011).

The combination of the male's own quality and the quality of the females available for mating can also mediate ejaculatory investment: Dominant cocks (*Gallus gallus*) are more prudent in their ejaculatory investment than subordinate males. Dominant males mate more often, and they allocate more sperm to high-quality females, whereas subordinate males have similar ejaculatory investments in the few matings they can achieve.

Ejaculatory Capacity in Humans

Depletion of the extragonadal reserve of sperm in men is rapid, occurring on the second day after an average of 2.4 ejaculations per day, with significant declines in ejaculate volume (47%), sperm concentration (67%), and total sperm (84%) during this period (Freund 1963). During the follow-up period, the numbers of sperm remained well below the original counts before the beginning of the experiment (Freund 1963), suggesting that sperm depletion is a real risk for men after repeated ejaculation and, therefore, that strategic sperm allocation may be evolutionarily favored. Other studies have supported the generality of these findings (reviewed in Shackelford et al. 2005).

Evidence of Ejaculate Adjustment in Humans

In humans, ejaculate adjustment was reported in a study where the authors tested the hypothesis that men may inseminate more sperm to their partners after they had spent time apart, presumably because they could not have mated guarded (Baker and Bellis 1989). Ten couples used a condom to collect ejaculates resulting from intercourse, and their sperm counts were compared to those of ejaculates collected through masturbation. Data from how much time they had spent apart prior to the copulation were collected, and the authors reported that sperm numbers were

significantly correlated with the percent time the couples had spent apart prior to copulation, while no such correlation was found for the masturbation samples (Baker and Bellis 1989). In a follow-up study that added a large survey to investigations of ejaculate number, Baker and Bellis again reported a correlation between sperm numbers and time apart prior to copulation, but their sample sizes continued to be very small (out of 33 recruited pairs, only 15 males produced repeated intra-pair copulation samples, and most did not produce masturbation samples) (Baker and Bellis 1993). They also concluded that men inseminate larger numbers of sperm to larger females (heavier and taller), consistent with the idea that males should adjust their ejaculate when mating with higher-quality females. From the survey data on 3,679 women, they concluded that time apart did in fact reflect the risk of sperm competition, as women who reported having extra-pair sex were more likely to do so when they were apart from their partner.

Although their results are intriguing, Baker and Bellis' studies are correlational in nature, suffer from lack of controls, and small sample sizes (Shackelford et al. 2005; Leivers et al. 2014). Unfortunately, no recent experimental studies with large sample sizes have followed up Baker and Bellis's studies.

The quality and quantity of ejaculates collected from copulatory activities compared to ejaculates collected from masturbation are known to be different (Shackelford et al. 2005). Although this hints at the potential for strategic sperm allocation to take place to avoid wasting too much sperm during masturbation (Shackelford et al. 2005), better/larger ejaculates may be a nonadaptive consequence of higher levels of arousal during copulation when compared to masturbation. Men produce better ejaculate samples through masturbation when allowed to view erotic materials, again perhaps because such materials produce higher arousal levels.

Perceived sperm competition while viewing erotic materials seems to result in ejaculatory adjustment. Men express a preference for erotic materials that depict multiple males engaged in sex with one female than a single male having sex with multiple females as evidenced by sales of

erotic DVDs (McKibbin et al. 2013). This preference seems to be translated into ejaculate quality. When viewing erotic materials, males produced a higher-quality ejaculate when the material included two men and one woman than when it only included three women, presumably because men were viewed as potential competitors (Kilgallon and Simmons 2005). And just as is the case in cocks, ejaculate investment in men can be context dependent, according to the male's own mate value. Men that were rated as having higher mate value invested more in ejaculates only when viewing erotic images of women deemed to be of higher quality (Leivers et al. 2014).

Men have also been found to produce better ejaculates when exposed to novel females during a porn viewing experience (Joseph et al. 2015), just as predicted by the Coolidge effect. Males were exposed to erotic images of the same woman six times, before being exposed to a novel woman. Contrary to expectations, this study failed to find a decrease in the measured ejaculatory parameters between times 1–6 of exposure, perhaps because the men in the study had ample time to recover between exposures (48–72 h), but the introduction of novelty resulted in a significant increase in sperm motility, and ejaculate volume, and a decrease in ejaculation time (Joseph et al. 2015). The extraordinary success and addictive power of easily available porn in the Internet seem to take advantage of men's increased sexual interest in young, diverse, and fertile females. More studies are beginning to delve into the patterns of porn consumption in men and whether these can at least partly be explained by our evolutionary history.

Conclusion

The studies mentioned above provide evidence that ejaculatory adjustment as a response to extrinsic factors appears to be found in men. However, the studies are still relatively few and many are very recent. More experimental evidence testing the general applicability of evolutionary sperm allocation still needs to be gathered. This is

particularly important because ejaculate components such as volume, sperm number, and quality can be highly variable, not only between males depending on their intrinsic factors as mentioned above, but within males (Freund 1963). In his discussion of semen production in men, Freund states that

it is evident that without repeated specimens under controlled conditions, no estimate of the variation among specimens within donors can be made. Without such an estimate of within donor variation, no conclusive test of the significance of the differences among donors, among fertile and infertile groups, or among or among treated and control groups, can be made.

Therefore, experiments with larger sample sizes that control for known factors that cause intrinsic variation of ejaculate quality are badly needed to determine the relative importance of strategic sperm allocation and sperm prudence in men.

Definition

Male traits and sexual behaviors that predict the likelihood of female orgasm.

Introduction

In contrast to male orgasm, the female orgasm is enormously variable in frequency during penetrative sex. While men almost always ejaculate during penile-vaginal intercourse, women orgasm far less frequently from penetrative sex alone and experience significant variation in orgasm frequency with different partners (Lloyd 2005). While variation in women’s orgasm frequency is poorly understood, evolutionary psychology tends to view variation in behavior as adaptive and responsive to environmental conditions.

Current evolutionary theories regarding the female orgasm can be broadly divided into two positions: those that focus on selection on male sexual function and those that focus on selection on female sexual function. The by-product hypothesis concerns the former and posits that the capacity of women to experience orgasm is a consequence of strong selection pressure on males’ capacity to reach orgasm. This position is based on similarities between male and female orgasm as well as the observation that the male glans penis and female clitoris arise from homologous tissue during development. In contrast, the mate choice hypothesis argues that variation in female orgasm frequency during sexual intercourse is reflective of varying quality of their male partners. Increased orgasm frequency with men possessing desirable traits ought to promote repeated copulations, thus increasing the likelihood of impregnation. This position can be further distinguished by predictions regarding which male traits are likely to influence orgasm frequency.

Mate-Choice Hypotheses of Female Orgasm

Given the high gestational cost of rearing human offspring women should be driven to select mates of high quality. Under the *sire-choice hypothesis*,

quality tends to be defined as the ability to pass favorable genetic traits onto offspring (i.e., heritable traits) that will contribute to offspring fitness. In contrast, the *pair-bonding hypothesis* postulates that male traits that are likely to benefit the woman through increased care and investment in offspring ought to promote orgasm. Traits that have been identified as theoretically important to each theory can be seen in Table 1 below.

Mate-Choice Traits that Predict Orgasm Likelihood

Sire-Choice

The sire-choice hypothesis has been more extensively tested than the pair-bonding hypothesis and some evidence does suggest that women may be more likely to orgasm when their partner possesses traits putatively associated with genetic quality. For instance, several studies have observed that women report higher orgasm frequency with more physically attractive partners (Andersson 1994; Gallup et al. 2014; Grammer et al. 2003; Shackelford et al. 2000). While some of these studies may be subject to bias in the cases that women self-reported their partner’s attractiveness (Gallup et al. 2014; Shackelford et al. 2000), others have obtained independent ratings of male attractiveness, which also corresponded to increased likelihood of orgasm (Puts et al. 2012; Thornhill et al. 1995).

Pair-Bonding

Few studies to date have thoroughly investigated pair-bonding traits in the context of female

Male Qualities and Likelihood of Orgasm, Table 1 Partner traits distinguishing mate-choice hypotheses (For review see Sherlock et al. 2016)

M

orgasm frequency. However, Costa and Brody (2007) have observed that greater orgasm frequency is associated with overall relationship quality. Moreover, Gallup et al. (2014) found that women reported greater orgasm frequency during penile-vaginal intercourse when their partner's family had a higher income, suggesting a role for resource provision. It should be noted that neither Thornhill et al. (1995) or Zietsch et al. (2011) replicated the relationship between orgasm frequency and relationship length or commitment, calling into question the validity of the pattern found by Costa and Brody (2007).

Alternative Considerations

While some male traits have been reported to covary with orgasm frequency, this may not represent a causal relationship. Firstly, it is possible that women who orgasm more frequently may be more likely to select particular types of partners than women who orgasm infrequently. For example, women who report a higher orgasm frequency may choose to have sex with more physically attractive men. These men are likely to have more experience in short-term sexual relationships and therefore may be more effective at eliciting orgasm in their partners. Additionally, OkCupid report that of over 42,000 female users, women who reported that exercise is enjoyable also reported reaching orgasm more easily (Rudder 2011). These women, who likely exercise more frequently, may be more attractive themselves and thus more likely to partner with attractive men (Sherlock et al. 2016). Secondly, women vary considerably in their capacity to achieve orgasm, even when masturbating. This variation between women makes it difficult to detect consistent relationships between orgasm frequency and the traits of male sexual partners. However, studying the nature of variation in the same woman's orgasm frequency with different male partners avoids these issues.

Only one study to date has investigated how women's orgasm frequencies have varied with different sexual partners. Sherlock et al. (2016) had single women with more than two male sexual partners report on a range of characteristics of the man with whom orgasm was the easiest and

the man with whom orgasm was the most difficult (or did not occur at all). By comparing high- and low-orgasm men, several traits emerged as important in predicting ease of orgasm. High-orgasm men tended to be higher in humor, attractiveness, creativity, emotional warmth, faithfulness, and body odor pleasantness, consistent with both sire-choice and pair-bonding hypotheses.

Male Sexual Behavior

Importantly, Sherlock et al. (2016) also observed that a number of sexual behaviors differed between high- and low-orgasm males. Specifically, high-orgasm males were more likely to be focused on their partner's pleasure, engage in oral sex, use sex toys, spend more time on foreplay, and stimulate their partner's clitoris during sex. Women were also more likely to communicate their sexual position preferences and stimulate their clitoris when having sex with high-orgasm partners. These results are consistent with two large-surveys of female orgasm during last sexual encounter. Richters et al. (2006) surveyed 19,000 Australians regarding their last sexual encounter and found that the likelihood of a woman orgasm was predicted by the number of sexual practices (i.e., oral sex, digital stimulation, etc.) engaged in prior to intercourse. More recently, Frederick et al. (2017) found that, in a survey of over 50,000 American adults, women who orgasmed more frequently were more likely to receive oral sex, use varied sexual positions, and communicate their sexual desires. Across all three studies, orgasm was more likely to occur with manual stimulation of the clitoris during intercourse (Frederick et al. 2017; Richters et al. 2006; Sherlock et al. 2016). Consequently, any contribution of male traits (e.g., attractiveness) to female orgasm needs to be considered in the context of variation in male sexual behavior. Further complicating these results is the likely association between male traits and sexual behaviors. For example, finding that women orgasm more frequently with men who exhibit higher warmth and empathy could be interpreted as support for the pair-bonding hypothesis: these men may be kinder and more generous spouses/fathers. However, an alternate explanation may be that men

with higher warmth and empathy are more likely to attend to their partner's pleasure during sex.

Conclusion

Despite some consistency in male traits associated with orgasm across several studies, there is reason to be cautious interpreting these results without first accounting for male sexual behavior. The most prominent trait associated with increases in the likelihood of female orgasm is attractiveness (Andersson 1994; Gallup et al. 2014; Grammer et al. 2003; Shackelford et al. 2000; Sherlock et al. 2016), yet the causal pathway between attractiveness and female orgasm could be inverse to the current theorizing. That is, women could come to view their partners as more attractive if they are more frequent benefactors of orgasms. In sum, the most consistent findings regarding males who elicit orgasm more frequently pertain to their sexual behavior rather than their traits. Women are more likely to achieve orgasm with a partner who is attentive, patient, and receptive to instruction.

Male Reproductive Variance

Kelly A. Stiver

Psychology Department, Southern Connecticut State University, New Haven, CT, USA

Synonyms

Differential male reproductive success

Definition

Within species or breeding population variation in male reproductive success.

Introduction

Within a species, individuals vary in reproductive success. In a sexual reproducing species, where

each individual has one male and one female parent, increased reproductive success for certain individuals of one sex necessitates decreased reproductive success for others of that sex. Put more directly, the more extreme the winners, the more extreme the losers. While the focus of this entry is male reproductive variance, it will by necessity to also discuss female reproductive variance as a contrast, as reproductive variance is a major factor both of and contributing to sex differences, which coevolve with both mating strategies and parental care.

Coevolution with Parental Investment/Care

Across species, males tend to show greater variance in reproductive success than females. This results from females typically having a lower potential reproductive rate relative to males; a fundamental difference is rooted in anisogamy – differential investment in gametes by males versus females, the basis of sexual reproduction. Parental investment is defined as investment in one offspring (or current offspring) to the exclusion of other (particularly future) offspring (Trivers 1972). Because energetic and time investments in particular offspring come at the cost of investing in different behaviors or young, exclusionary efforts toward any particular reproductive event comes at the cost of continued investment in past reproduction, or investment in potential future reproduction.

Even if the only parental investment in a species is initial gamete production, females are obligated to a higher per-offspring investment than males, and this initial difference in investment is thought to be the ultimate basis of the general tendency toward females having higher parental investment than males (Trivers 1972). This difference can be more profound in species such as mammals where females have obligate parental investment far beyond gamete production. Looking at humans as a sample mammal, the maximum recorded number of putative offspring for a man is ~888 (Oberzaucher and Grammer 2014), 12.9 times the maximum of 69 recorded for a woman (in 27 pregnancies, all births were

multiples; Guinness World Records 2016). The fact that females tend to be the “slower” sex – that is, requiring more “time-out” between or resource input into reproductive events – has the consequence of their typically being the limiting sex. Therefore, males, as the usually more reproductively available sex, are faced with a higher likelihood of being excluded from reproduction (as above, because every offspring has one-and-only-one male and female genetic parent), resulting in male variability in reproductive success being typically higher than that in females (known as *Bateman’s principle*; Bateman 1948).

This difference in reproductive success variation *tends* to result in males being relatively more competitive for access to mates (females being a limiting resource for reproduction; Trivers 1972) and females being relatively more choosy about potential mates. It should be noted that this does not exclude the possibility that both sexes are both competitive and choosy – there is no expectation that males mate *indiscriminately* nor that females do not vie for the more valuable (in terms of direct resources or good genes) males. Rather, it means that on average, males will be more engaging in intrasexual competition over mates than females, and females will be more choosy over mates than males.

Coevolution with Mating Systems

Generally speaking, the degree of variation in reproductive success within a sex is closely tied to the species-typical mating system (Davies et al. 2012). For examples, in species where the typical mode is monogamy, both males and females show relatively low reproductive variance, particularly in comparison with systems where females (polyandrous), males (polygynous), or both sexes (promiscuous) have simultaneous multiple mates. However, even in monogamous systems, there is room for variation (e.g., Brown et al. 2009). For example, individuals may differ in their likelihood of ever entering a partnership (e.g., particularly if there is a biased sex ratio), and the number of lifetime partnerships may differ between individuals (and also between the sexes).

Among humans, cultural variation in “exclusive sexual partnerships” or marriage practices is associated with the reproductive variance in the sexes in those cultures. In relatively few cultures, women are exclusively sexual with multiple men (in several of these examples, these men are related to one another), but men “officially” have sexual access only with her. These cultures are often ones where the “cost” of obtaining a wife is high, or there are few available women due to some other cultural or life-history factor (Starkweather and Hames 2012).

More frequently documented are polygynous cultures, where one man monopolizes sexual access to multiple women (this may be associated with strict control of women to prevent her having sex with other men; Chamberlin and Guiora 2014). Such societies often have associated with them reproductive control or expulsion of other men (typically subordinates, sometimes involving castration of non-evicted men; Chamberlin and Guiora 2014). However, not all polygynous cultures have such high male skew, and societies noted as polygynous may express a more mild form of occasional polygyny in the context of overall monogamy or increased re-pairing by men relative to women (e.g., Brown et al. 2009). In fact, many cultures identified as monogamous may be better, from a behavioral ecology perspective, be labelled as mildly polygynous, particularly due to the commonality of serial monogamy.

Complicating matters is the fact that studies frequently show that men *on average* report a higher number of sexual partners than women; while this likely results in part from opposing cultural pressures that drive men to overreport and women to underreport their number of partners, other factors (such as access to sex workers, who are not subsequently surveyed) can help explain this discrepancy. Overall, humans appear to, on average, broadly fit a pattern of moderate polygyny, and male reproductive variance is typically higher than that of females (e.g., Hammer et al. 2008), although as above, this is rather variable, and unlike many animal species, it is difficult to identify a clearly “typical” human mating system, as there is considerable variation of

form even within these broad categories (see discussion in Brown et al. 2009).

Consequences of Variation in Male Reproductive Success

Sexual selection influences the degree of reproductive variance observed within the sexes, and evolution of mating strategies in response to differential reproductive success further propagates sexual selection. The effects of male reproductive variance on mating systems have resulted in myriad complicated expressions of male reproductive behavior, and differential reproductive success among males is often associated with variation (either discrete or continuous) in other aspects of their morphology and reproductive behavior (e.g., Davies et al. 2012). Note that similar variation between sexes within a species (sexual dimorphism), though not invariably the result of sexual selection, can also be rooted in a difference in reproductive success variation between males and females (Davies et al. 2012). For example, if certain traits permit males access to mates through mate preference or through competition, those traits will tend to evolve to become sexually dimorphic (for an extreme example, consider the anglerfish, where females are up to half a million times heavier than males, who become functionally parasitic on the female they adhere to; Pietsch 2005).

The most striking examples of reproductive success coevolving with male reproductive phenotype can be observed in nonhuman animal species where males show profound within-species variation in individual morphology and reproductive behavior. These reproductive phenotypes may represent different life-history pathways (e.g., Ruffs, where alternative types also have a genetic basis; Lank et al. 1995), or different life stages (e.g., orangutans; Knott 2009), with the result males may or may not exhibit multiple reproductive phenotypes in their lifetime. Among fishes, males in species with alternative male tactics may display clearly discrete morphological and behavioral phenotypes, to the extreme that males of the same species may appear to the

naïve observer to be different species (see Taborsky 1994 for an overview of alternative reproductive tactics among fishes). Certain avian species and mammalian species also show similar, though often less profound, discrete variation in male reproductive phenotype (e.g., Leboeuf 1972; Lank et al. 1995; Knott 2009). Typically, alternative phenotypes are associated with different levels of reproductive success, although the strategy with the highest lifetime reproductive success is not necessarily always those large showy dominant males (e.g., Berejikian et al. 2010).

More typically, differences in male reproductive success are correlated with continuous male trait variation of traits involved in mate attraction or intrasexual competition (see overview in Davies et al. 2012). Such traits may be associated with ability to sequester resources (e.g., energetic reserves or mating resources such as territories), attract mates (e.g., by signaling genetic quality, compatibility, or ability to provide direct benefits to offspring), or outcompete other males for mating access (e.g., traits that enhance strength or stealth). Males who possess traits that allow increased control of reproductive resources and potential males have increased individual reproductive success.

From a comparative perspective, the phenotypic variation seen among human males in likely response to reproductive success variation is relatively muted. Data are restricted as there are relatively few studies of human reproduction that directly assess offspring number and outcome; far more frequently examined is mating success or partnership formation. That said, some male traits have been shown to be predictive of reproductive success, both production and survival of offspring, with the caveat that putative offspring are not necessarily fathered by that man, and males may underreport offspring resulting from women they do not have an official partnership with. Relationships are typically in the continuous fashion described above, although it is not always a linear correlation. These traits include voice pitch (Apicella et al. 2007); performance in ritual fights (Llaurens et al. 2009); physical traits such as height (average or moderately tall being most

successful; Nettle 2002; Stulp et al. 2012), weight (Schooling et al. 2011), BMI (Sear 2006), and upper-body strength (Apicella 2014); hunting ability (Kaplan and Hill 1985; Smith 2004); personality (Alvergne et al. 2010); and wealth/higher socioeconomic status (Nettle and Pollet 2008). Also, as males with higher reproductive success are typically judged as more physically attractive (e.g., Jokela 2009), we can expect that some factors correlated with perceived attractiveness should also predict reproductive success. Additional traits that would be expected to correlate with traits above have been shown to be predictive of mating success, and it is therefore reasonable to presume that they are also likely predictive of reproductive success.

Conclusion

Reproductive variance coevolves with parental investment and mating system and influences and is influenced by sexual selection pressures. The initial bias of increased parental investment by females relative to males is related to the typical cross-taxa finding of greater reproductive variance among males than among females. Degree of variation within and between the sexes is tied to mating, and there is a feedback loop between the forces and consequences of sexual selection resulting from male reproductive variation. In nonhuman animals, the consequences of reproductive variance among males can be extreme variation in reproductive phenotype (both morphology and behavior). Similar variation related to reproductive success can be observed in a less elaborate and typically more continuous fashion among human males.

Male Sexual Jealousy to Deter Partner Infidelity

S. Ladwig
Florida State University, Tallahassee, FL, USA

Synonyms

[Cuckoldry](#); [Paternity uncertainty](#)

Definition

The jealousy males feel about female infidelity as an evolutionary reaction to internal female fertilization and paternity uncertainty.

Introduction

When infidelity occurs, males and females experience different biological and social costs. As such, they have developed different reactions toward infidelity. For males, one common reaction is sexual jealousy in order to deter partner infidelity.

The Costs of Infidelity

In species with internal female fertilization, partner infidelity has different costs for males and females. If a male's mate has sexual contact with other

males, the male has a lesser probability of impregnating his mate, and he has greater paternity uncertainty. If the rival male successfully impregnates his mate, the male will have lost the time, energy, nuptial gifts, the female's parental effort, and the opportunity of mating with other females (Buss et al. 1992). Furthermore, in biparental species, where males invest in their offspring after birth, he may unknowingly invest resources in the rival's offspring (Trivers 1972). Because human males invest a great deal in their offspring, evolutionary selection pressures have led to the development of strategies which allow men to exert sexual control over women in order to prevent infidelity (Daly et al. 1982; Nannini and Meyers 2000). Sexual jealousy is one such strategy to prevent cuckoldry.

On the other hand, females do not incur the same costs as males. Regardless of her mate's infidelities, the female is certain of her own maternity. However, infidelities can be costly in other ways for females, as females risk losing the resources, energy, and time of their mates if the male chooses to invest in a rival female. As such, females have been evolutionary driven to be more sensitive to cues of her mate's emotional investment with another female. In this case, emotional infidelity may be more disastrous than sexual infidelity.

Studies of Modern Humans

Studies of undergraduate students have confirmed that males tend to react more strongly – with both jealousy and anger – to sexual, as opposed to emotional, infidelity. Buss et al. (1992) found that 60% of males and only 17% of females reported that sexual infidelity was more distressing than emotional infidelity. The researchers also used physiological measures that recorded sweat activity, pulse rate, and facial activity while subjects imagined various cheating scenarios. Overall, males displayed greater and more consistent physiological signs of jealousy and distress. This research has been replicated in cross-cultural studies as well (Buunk et al. 1996).

Researchers have also studied incidents of intimate partner violence, and they consistently find

that male sexual jealousy is one of the leading motivators for this kind of violence (Daly et al. 1982; Daly and Wilson 1988). Women are most likely to experience battery when her partner either suspects that she is ending the relationship or that she has engaged in sexual infidelity (Daly and Wilson 1988). Both experimental and observational studies therefore show that sexual jealousy is more common among men.

Competing Explanations

Some researchers suggest that the observed differences in male and female jealousy may be due to issues with the validity of measures. This hypothesis, known as the *double-shot hypothesis*, posits that men and women interpret infidelity differently (DeSteno and Salovey 1996). Men are more likely to believe that if a sexual infidelity has occurred, then an emotional infidelity has also occurred. However, in their view, an emotional infidelity can occur without any sexual infidelity. Women are more likely to believe that if an emotional infidelity has occurred, then a sexual infidelity has occurred as well. In their view, a sexual infidelity may occur without an emotional infidelity. Therefore, when asked to pick which scenario is more distressing, each gender will be more likely to choose the scenario in which they think it is likely that both types of infidelity have occurred: men will be more distressed by sexual infidelity, and women will be more distressed by emotional infidelity. In reality, according to this perspective, both men and women are equally distressed by the co-occurrence of both types of infidelity.

Researchers have redesigned studies in order to account for this possible artifactual relationship. When asked to imagine that only one infidelity had occurred, and when asked to imagine that both types of infidelities had occurred, males were more likely to list the sexual infidelities as more distressing, while females were more likely to state that the emotional infidelity was more distressing (Buss et al. 1996). These results show that there are real jealousy differences between males and females.

Other Means of Ensuring Paternity

Jealousy is a tactic meant to prevent infidelity, but in case infidelity occurs, males also have other methods to ensure that they do not invest in another male's gametes (Shackelford and Goetz 2007). Sperm competition strategies may have also developed to decrease the likelihood that another male's sperm will impregnate the female. Differential parental investment, where males invest less in their offspring than females, also decreases the amount of resources that will be allocated to a rival's offspring.

Conclusion

While it is unknown how common cuckoldry was in early human history, one study suggests that between approximately 9% and 13% of modern children have putative fathers who are not actually their genetic fathers (Baker and Bellis 1995). This rate of cuckoldry suggests that there was significant risk of males unknowingly investing in another male's offspring, and this risk may have been sufficient enough that evolutionary selection pressures would develop a mechanism to prevent cuckoldry. Current theories thus suggest that male sexual jealousy developed as a means to deter partner infidelity and the associated paternity uncertainty. This jealousy can range from trivial annoyance to fatal violence.

Male Warrior Hypothesis

Definition

The male warrior hypothesis is an evolutionary theory that refers to the idea that men’s behaviors and cognitions are more strongly intergroup-oriented than women’s, such that men likely evolved psychological mechanisms that enable the formation of coalitions that are capable of carrying out acts of aggression and violence on members of outgroups as a means to acquire or protect reproductive resources. These mechanisms are purported to have developed as the result of an ancestral history that was largely influenced by frequent and violent intergroup conflict among males, in which success increased their reproductive fitness.

Introduction

Due to reproductive and survival benefits, humans (and other species) tend to come together in groups (Baumeister and Leary 1995). Although

costly, intergroup conflict is, and has been, pervasive among humans (Bowles 2009). When these conflicts involve acts of aggression and violence, research finds that, across time and cultures, men are almost exclusively the perpetrators of such acts (e.g., Goldstein 2003). This greater propensity to engage in intergroup violence and aggression is suggested to have evolved in men due to the resulting benefits to men's reproductive fitness (e.g., Buss 1999; Van Vugt 2009; Van Vugt et al. 2007). Men's reproductive fitness is limited by access to fertile women, whereas women's fitness is limited by physiological, energetic, and resource constraints (e.g., Buss 1999). Thus, men, but not women, can increase their fitness by maintaining exclusive access to large numbers of mates, which can be accomplished through intergroup conflict (e.g., McDonald et al. 2012). That is, groups of successful men in intergroup conflicts may reap the benefits of increased access to mates and gains in prestige. Indeed, research conducted on traditional (i.e., tribal) human societies finds that male warriors have more mates and children and enjoy higher status than other men (Chagnon 1988) and young male street-gang members have been found to have more sexual partners than other young males (Palmer and Tilley 1995). Thus, evolutionary psychologists assert that men may have evolved psychological mechanisms for forming coalitions that are able to plan and execute aggressive attacks on members of other groups and should be more intergroup oriented in general, than women (e.g., McDonald et al. 2012; Van Vugt et al. 2007). This is known as *the male warrior hypothesis* (McDonald et al. 2012; Van Vugt 2009; Van Vugt et al. 2007).

Support for the Male Warrior Hypothesis

The male warrior hypothesis asserts that men are more intergroup oriented than women and have evolved psychological mechanisms that increase the potential for success in intergroup conflicts (e.g., Van Vugt et al. 2007). Evidence for the operation of these mechanisms can be found in research examining the conflict-relevant thoughts, emotions, and behaviors of men in modern

societies (McDonald et al. 2012). Although inclusion of all such research is beyond the limits of this entry, examples of empirical support for some of the major predictions of the male warrior hypothesis, specifically in the areas of intergroup aggression, prejudice, preference for intergroup hierarchies, and ingroup identification and cooperation, are discussed.

The most basic prediction of the male warrior hypothesis is that men should be more likely than women to initiate and engage in aggressive intergroup behavior because success in intergroup conflicts likely increases access to mates and other resources. This prediction has also largely been supported across many studies. As stated previously, in instances of real-world violent intergroup conflicts such as warfare, genocide, and street-gang violence, groups of men are almost exclusively the perpetrators (e.g., Goldstein 2003). And warrior males have also been found to have more mates and children, as well as higher social status (e.g., Chagnon 1988) than other males. Further, on a daily basis, men tend to report a higher frequency of competitive intergroup interactions than women (Pemberton et al. 1996; Van Vugt 2009). These aggressive tendencies have also been found in laboratory manipulations. For example, in one particularly interesting study, pairs of participants played a simulated wargame in which they were asked to imagine that they were the leader of a fictitious country in conflict with another country over newly discovered resources (Johnson et al. 2006). Results revealed that men were significantly more likely than women to attack the other country without provocation and were also more confident that they would win the conflict. Interestingly, even though participants were unaware of the sex of their rival, pairs of male participants yielded the most intense warfare, whereas pairs of female participants yielded the least. In further support for the male warrior hypothesis, men's propensity towards intergroup conflict appears to be specifically tied to mating motives. In a series of studies, Chang et al. (2011) examined whether activating mating motives would increase participants' access to war-related cognition and perception. Men, but not women,

exposed to attractive, opposed to unattractive, opposite-sex photos were more likely to endorse pro-war statements, but not trade-conflict statements. In addition, men who were primed with attractive faces or legs of women, as opposed to unattractive faces of women and national flags, responded significantly faster to war-related words and images, but not farming-related words and images or expressions of general aggression. Taken together, the preponderance of evidence suggests that men are more inclined to engage in aggressive or competitive intergroup behavior than are women, and this tendency appears to be related to mating motives.

The male warrior hypothesis also predicts that men should harbor more derogatory and prejudiced attitudes about outgroup members because this may reduce the psychological discomfort that might result from harming these individuals during violent conflicts (e.g., McDonald et al. 2012). Research has generally supported this contention. Men tend to be more xenophobic and ethnocentric than women (e.g., Ekehammar and Sidanius 1982) and are also more likely to dehumanize outgroup members (i.e., describe them using animal-like words) than are women (e.g., Van Vugt 2009). Further, men are more likely than women to describe outgroup members using danger-related stereotypes when in conditions of ambiguous threat (i.e., when primed with ambient darkness; Schaller et al. 2003). Thus, men do appear to harbor more prejudiced and derogatory attitudes about members of outgroups than women.

Intergroup conflicts inevitably result in intergroup hierarchies because some groups will be more successful than others. As a result, the male warrior hypothesis predicts that men should exhibit a stronger preference for intergroup dominance hierarchies than women (Van Vugt 2009). Consistent with this prediction, in samples taken from a variety of countries and cultures men consistently score higher in social dominance orientation (SDO; i.e., general preference for hierarchical, dominant-subordinate intergroup relations as opposed to more equal intergroup relations; Pratto et al. 1994) than do women (e.g., Lee et al. 2011; Van Vugt 2009). Of particular

importance, higher scores in SDO are associated with a variety of beliefs and attitudes that serve to maintain and justify group-based hierarchies such as political-economic conservatism, meritocracy ideology, nationalism, patriotism, and cultural elitism (e.g., Lee et al. 2011). These results suggest that men do prefer intergroup hierarchies more than women and are perhaps also more likely to harbor beliefs that are involved in maintaining and supporting existing intergroup hierarchies.

Finally, the male warrior hypothesis predicts that men should be more motivated to protect and support the ingroup, especially when threatened by or in competition with another group, because success in intergroup competitions depends, to some extent, on one's ingroup being cohesive, strong, and coordinated (Van Vugt 2009; Van Vugt et al. 2007). In accordance with this prediction, across three studies using a public goods game Van Vugt et al. (2007) found that men increased cooperative donations to their ingroup when in competition with other rival groups, as opposed to a condition in which participants were in competition with other individuals, whereas women's cooperative donations to their group were seemingly unaffected by competition condition. In the same study, men, but not women, also reported stronger identification with the group in an intergroup competition condition than in an interindividual competition condition. Interestingly, men's identification with the group fully mediated the association between their increased cooperative donations and competition condition. Relatedly, research also suggests that men may generally identify more strongly with groups than women. For example, Van Vugt (2009) asked 100 college students to state their favorite color and explain why this particular color was their favorite. Results indicated that 30% of men chose a color because it was associated with an ingroup (e.g., a favorite sports team), whereas no women gave this sort of explanation. Further, Gabriel and Gardner (1999) asked participants to complete the statement "I am..." and found that men were twice as likely as women to make a statement about a group membership (e.g., being a member of a fraternity or being an

American). Taken together, these studies suggest that, when intergroup competition is salient, men are more likely than women to increase cooperation with their group and are also more likely to personally identify with membership groups than women.

Conclusion

The male warrior hypotheses is an evolutionary theory that states men have evolved psychological mechanisms that enable the formation of coalitions that are capable of carrying out acts of aggression and violence on members of outgroups as a means to acquire or protect reproductive resources. The major predictions of the male warrior hypothesis have been largely supported in both examinations of trends in real-world intergroup conflict and laboratory examinations. It is hopeful that future investigations of the predictions of the male warrior hypothesis, and other related theories, will continue to shed light on intergroup behavior and the evolved psychological mechanisms that play a role in such behavior.

Definition

Male-Male Competition: Competition between males for access to females.

Introduction

Contest competition in males (male-male competition) is a driving force in sexual selection (Puts 2010). For males, successful competitive displays increase access to valuable resources (e.g., territory, food), mates, and an increase in status. Some mechanisms favor success in male-male competition, such as aggressive behavior and physical characteristics that increase the facilitation of aggressiveness (i.e., size, strength, weaponry). For instance, sea lions establish their dominance through threats and fights, and this has important repercussions to their reproductive success. In a single breeding season, dominant males perform most of the copulations and sire a majority of pups (Daly and Wilson 1983). This intense competition between males was noted in Bateman's classic 1948 study on sex differences in reproductive strategies using *Drosophila*. Because males are dependent on females for their reproductive success, sexual selection, in this case, intrasexual selection, is stronger in males than females. Males can increase their reproductive success by increasing their mating frequency, and to be reproductively successful, they must compete with other males to access those females (Bateman 1948; Darwin 1859).

In human populations, male-male competition reflects similar behaviors observed from non-human species. Competition between males is driven by gaining access to fertile females in an attempt to maximize reproductive success (Daly and Wilson 1983) and in accessing resources and establishing dominance in status hierarchies (Geary 1999), which nonetheless influence reproductive behavior. In preindustrial societies, such as indigenous tribes in South America, conflict is perpetrated by males with motives in gaining status to appeal to prospective female mates as marriage partners. Intergroup conflict between tribes has shown to result in capturing territory,

resources, and women to take as wives which leads to higher reproductive success (Geary 1999). In nomadic pastoralists in East Africa, elders who had a history of engaging in raids throughout their youth had a higher number of wives and children, suggesting that raiding afforded reproductive opportunities (Glowacki and Wrangham 2015). Even in current industrial societies, violent acts are perpetrated by men against other men. Acts of violence are often in response to competing interests, such as access to resources, increases in social status, and in response to sexual jealousy. Since these interests carry fitness consequences, they are valued by men, and competition is stronger for men than they are for women (Daly and Wilson 1988). In violent and homicidal data reviewed by Daly and Wilson (1988), across many societies (e.g., pre-industrial and industrial), homicides are most likely to be committed by men killing other men, with motives ranging from insult to status, domestic issues, sexual jealousy, and attempting to access resources (e.g., robbery) (Daly and Wilson 1988).

Male-Male Competition in Early Development

Evidence for male-male competition is apparent in early development. Compared to girls, infant boys show interest to videos depicting groups, which are an important function for coalitional activities (Benenson et al. 2004). Male physical aggressiveness is apparent at a young age as boys engage in more play fighting and rough and tumble play than females (DiPietro 1981). Male competitive behavior intensifies in adolescence and tends to become more violent compared to childhood. Bullying in males is more likely to include physical aggression, and in adolescence, it is associated with social dominance (Bukowski et al. 2000). Aggressive behaviors in young males are likely to function as a way of establishing social competitive skills, group-level competitive play, and dominance hierarchies (Byrd-Craven and Geary 2013; Geary et al. 2003).

Physical Features in Competition

Compared to women, men are stronger and more physically aggressive. Men have more upper-body mass and musculature compared to women, and the average man is stronger than the majority of women (Puts 2010). Sex differences in physical size suggest an adaptation to male-male competition, and similar conclusions can be made with other animal species that share intense same-sex competition and display notable sex differences in physicality. For instance, fighting ability and behavior associated with male-male competition can be inferred from physical features in males. Studies have shown that features, such as facial masculinity (Perrett et al. 1998) and high facial width to height ratio, can infer aggressiveness and dominance (Carre et al. 2009), which are important attributes in contest competitions. Height has also been shown to be a sexually dimorphic feature shaped by sexual selection. In a study investigating sex differences in height and competitiveness, height was positively associated with intrasexual competitiveness (Polo et al. 2018).

Men are also sensitive to the physical features that are important in contest competitions. For instance, men consider other men with physical characteristics that are considered optimal (e.g., high shoulder to hip ratios) as more attractive and view specific areas of male bodies longer, such as the chest region (Durkee et al. 2018; Pazhoohi et al. 2019). Males who weight lift are sensitive to physical features that are important in contest competitions. For example, males who body build are more likely to use anabolic steroids if they score higher on an intrasexual competitiveness scale and are at the beginning stages of their training (Harris et al. 2017). Much like other species who have sexual ornaments for contest competitions (e.g., elk), males have shown to increase their dominance and aggressiveness by growing out their beards. Even though beards do not increase fighting ability, they signal attributes that are consistent with competitive displays (Dixson and Vasey 2012).

Competition in Sports

Male-male competitive displays are directly observed in sports. Given that males physically compete for access to mates and are more physically aggressive, sports may function as a by-product for those motives as sports can be aggressive and coalitional and serve as an advertisement of mate quality (Deaner et al. 2012). Throughout history, males have been more involved in sports (Guttman 2004), male sports have had more prominence (Roberts et al. 1959), and males have been more interested in viewing sports (Ellis et al. 2008). In three studies examining sports involvement across the United States, males were more likely to play more frequently (study 1), in public (study 2), and be more involved in collegiate intramural sports (study 3) (Deaner et al. 2012).

Hormonal Influences

Hormonal mechanisms play a significant role in male-male competition. In chimpanzees, testosterone levels are higher for males that are high ranking compared to low-ranking males (Muller and Wrangham 2004). In humans, testosterone is related to dominance seeking in males, but not in females (Geary 1999). For instance, in same-sex competitive situations, testosterone levels increase when asked to compete with members of an in-group compared to members of an out-group, suggesting that testosterone influences competitive behavior with known members, as unknown members may pose a greater risk (DeSoto et al. 2009). However, when considering mating opportunities, average levels of testosterone are associated with competing with dominant males if the reward is a high-mate value female (i.e., low waist to hip ratio) (Borraz-Leon et al. 2018). Testosterone has also been implicated in influencing punishing behaviors. When given testosterone compared to a placebo, men were more likely to punish members for an unfair offer in an experimental study, linking its role to aggressive behavior (Dreher et al. 2016). Research has also found that testosterone is linked to adolescent behavior as a function of social context.

Adolescents with nonaggressive conduct disorder are more likely to have higher levels of testosterone if they also have deviant peers. Moreover, in the same study, testosterone in adolescence is also linked to leadership skills, which is an important attribute in dominance but also prosocial behavior (Rowe et al. 2004).

Conclusion

Variation in reproductive success is greater in males than females, and this is apparent in the physical and behavioral differences associated with competition. Evidence from across societies shows that males are physically aggressive early on in development and show interest in behavior associated with coalitional activities (i.e., groups, hierarchies). Male physical characteristics, such as muscularity and strength, reveal the degree of sexual dimorphism that is similar in other species with intense male-male competition. Male-male competition is further underscored by the role of testosterone in aggressiveness, dominance, and mate-seeking, which are similar in closely related species that share similar intrasexual competitiveness.

Synonyms

Cooperative breeding; Indirect care; Intrasexual competition; Paternal investment; Showing-off

Definition

The degree to which a male allocates resources towards competing with male conspecifics or providing indirect care towards mates and/or offspring in order to boost his reproductive fitness.

Introduction

Same-sex competition and intersexual choice are key components of sexual selection. Trivers (1972) proposed that, in sexually reproducing species, intrasexual selection and intersexual choice are related to sex-specific investments (energy, resources, time) in offspring. Sex differences in fitness opportunities and payoffs contribute to sex differences in mating strategies (Geary 2010). In many mammalian species, females are the more ecological sex, meaning their reproductive function is more directly tied to availability of resources like food and safety. Conversely, male reproductive function is more directly tied to reproductive opportunities, contributing to higher rates of physical male-male competition. Females often display more discerning intersexual choice (see: ► “Sexual Reproduction”, ► “Sperm Competition”, ► “Sexual Selection”, ► “Sexual Dimorphism”, and ► “Intersexual Competition” in this volume) than their male conspecifics. Human males are similar to many other mammals in these respects, although humans display more plasticity in their reproductive strategies and more paternal investment than other primates (Gray and Garcia 2013). The highly plastic reproductive strategies employed by human males confound whether men have primarily been shaped by selection to compete with other men or provision their families. Interpretation of contemporary data on male behaviors (such as hunting or breadwinning) that may shape fitness outcomes are fiercely debated (reviewed in Kelly 2013). This entry aims to frame male-male competition and provisioning within life history theory, and highlights the variability with which relevant behaviors can be expressed.

Life History and Socioecology Shape How Men Choose Between Competition and Provisioning

Whether men invest in higher rates of male-male competition or more paternal provisioning depends on intrinsic (e.g., measures of phenotypic quality) and extrinsic (e.g., sex ratio) variables. The expression of a male’s investment in these reproductive behaviors is highly dependent on socioecological context (reviewed in: Gray et al. 2019). A male’s partitioning of time and energy to competing male reproductive behavioral agendas (like mating and parenting effort) can be framed by life history theory. Humans have been characterized as a cooperative breeding species, given the regular involvement of allomothers such as fathers in childrearing. Humans exhibit a unique, derived set of traits including an extended period of dependency (childhood), yet short interbirth intervals (duration between successive births), which lead to “stacking” of dependent offspring (reviewed in: Anderson et al., in prep.; Meehan and Crittenden 2016). When framed in evolutionary and life history theory, each male (unconsciously) decides whether to boost his fitness by investing finite resources (e.g., kilocalories, time) in male-male competition (in order to acquire status, resources, prestige, cooperators, and mates) to ultimately have a greater opportunity to sire a larger quantity of offspring or in provisioning an existing pair bond (reproductive partner) and offspring. Paternal investment may increase offspring survival but likely has a more pronounced fitness effect in contributing to shorter interbirth intervals (Gray and Garcia 2013).

The decision to invest in intrasexual competition or provisioning is, in some ways, a false-dichotomy; an individual can pursue a spectrum of strategies which may not directly reduce to competition for a larger quantity of offspring or provisioning to increase the survival of existing offspring. Some forms of male resource provisioning can both serve as male competitive displays and provisioning. Where forms of male-male competition and provisioning are mutually

incompatible (and thus trade-off with each other), the dichotomy then has merit.

High levels of parental care (such as provisioning) are expected to be favored in socioecologies in which male care helps enhance direct reproductive rates and offspring reproductive potential. If male care has minimal impact on offspring outcomes, there is an increased pressure to mate guard, or if his absence is readily replaced by other allomothers (such as kin, or support from state-level organizations), then men may minimize parental involvement (favoring instead to boost their fertility through male-male competition). The level of provisioning by men is thus influenced by the opportunity costs of foregoing reproductive opportunities with other potential mates, and by the level of support anticipated from the mother as well as extended kin networks (Hrdy 2009).

These factors contribute to the variable and facultative levels of male parental investment observed across contemporary human socioecologies (Gray and Garcia 2013; also reviewed in: Kelly 2013). Furthermore, a male's life history pace (a fast-slow continuum determined by extrinsic risks including pathogen load, lack of caregivers, insecure attachment) may affect how early and how much a male attempts to reproduce, which can further map onto risky attempts at male-male competition in order to secure a mate. In sum, many factors including the evolution of human life history traits, ecology, developmental history, socioecology, and even sex-ratio (see: Geary 2010) may influence whether a male chooses to compete or provision. Proximate mechanisms such as testosterone fluctuations may provide insight into which external stimuli drive a male towards engaging in competition or predisposing him to invest in his mate and children (reviewed in: Gray et al. 2019).

Big Game Hunting: Competition, Showing-Off, and/or Provisioning?

This section describes scholarly ideas on hunting (often attributed as a male activity and a critical

one in the evolution of modern humans), and whether hunting returns can be interpreted as a form of male-male competition, or as a reliable means to provision kin. While men can compete (for reputation, jobs, status, etc.) or provision (financially, vegetable foods, honey, land, social capital) in a variety of venues, big game hunting among foragers remains an area of special attention among many researchers and thus provides a useful focal point for this discussion (Coddington and Kramer 2016). The relationship between big game hunting and reproductive success (RS) has garnered considerable attention among modern small-scale foraging populations. While contemporary (or recently studied within past decades or even centuries) hunter-gatherers are not direct analogues to prehistoric populations, they do provide a window into how men's behavior impacts their reproductive success in natural-fertility settings that more closely resemble those of their hominin ancestors than today's large urban communities.

Among forager societies, male hunting success is consistently tied to higher status, although hunting is not the only way men compete, pursue status, and/or boost their reproductive success (Coddington and Kramer 2016). Theoretically, hunting itself can be viewed as a form of male-male competition in which more successful hunters are viewed as more prestigious within their group. This could allow them to have more access to higher quality mates or simply be more visible within a community. Additionally, big game hunting could be a source of protein and micronutrients which are critical to a group and widely shared due to the large package size that a large kill would create (otherwise most of it could spoil). Men may additionally be sharing preferentially with their household, and while wider sharing would suggest a mix of showing-off (and thus reaping the benefits of "winning" the hunt) and provisioning for the whole group. Hunting itself is a hotly debated topic and may have had many effects related to factors such as increased brain size, tool use, and extended life histories.

So how could hunting lead to an increase in status, and is this a sign of men's work essentially

being expressed as male-male competition? A large literature suggests that there is a link between hunting, men's status, and reproductive success (reviewed in: Copping and Kramer 2016; Kelly 2013), although the exact mechanism for this process is controversial. Men could be signaling their underlying quality as a mate by successfully returning a kill, while also signaling personality features such as generosity by widely sharing game. In this form of male-male competition, group members (and females) would evaluate an individual male based on his success. In fact, it does appear that in many modern small-scale preindustrial foraging populations, individuals can and do recognize who is the "best hunter" (Kelly 2013; Marlowe 2010; Stibbard-Hawkes et al. 2018). Additionally, some evidence suggests that hunting big game is in fact a risky endeavor, with a low success rate, and thus males only hunt (rather than procure easier game or gathered foods) as a costly signal of their mate value (reviewed in: Kelly 2013). In this signaling model, hunting is a more self-serving behavior (relative to if it were strictly a provisioning behavior) and women's work allows the necessary buffer for men to be able to show-off. What exactly is shown-off and how is debated in this model? Stibbard-Hawkes et al. (2018) found that while Hadza hunters are recognized and rated based on hunting ability, it is not necessarily costly to signal through hunting (men feed themselves on the hunt and often bring back alternate foods when faced with failure), and it is unclear if hunting success directly leads to more mating opportunities. That said, it appears the best hunters are often rated as more attractive and often pair with the best foragers (Kelly 2013; Marlowe 2010).

A contrary view to this male-male competitive and status seeking view of hunting is one which supports the positive effects of a provisioning father. Male provisioning, in the form of hunting, can provide critical calories (with a high proportion of fat and proportion) during key moments in reproduction. Females take on a significant caloric cost during pregnancy and lactation while also having noteworthy reductions in their own ability to provision (reviewed in: Meehan and Crittenden 2016). Male provisioning could provide the

necessary buffer during pregnancy and lactation to allow for a reduced risk of infant mortality. Wide sharing (as opposed to sharing within a man's own household) confounds provisioning as a reason for hunting (i.e., men's work), but even if men are sharing for status, it does appear that in many cases the best hunters' families appear to be provisioned more by the group as a whole (Kelly 2013; Marlowe 2010). Pair bonding stability may be an additional benefit of male provision, in addition to increased female fertility (an additional fitness benefit to a provisioning male).

Synthesis and Conclusion

Whether men's work (including the focus here on hunting) is a form of male-male competition or provisioning likely varies along a spectrum, in which men are both simultaneously competing and providing based on a host of factors like those alluded to in preceding sections. Environmental factors such as big game availability, market integration, disease burden, sexual inequality, and cultural norms (along with many others) likely contribute to variation in and changing forager male reproductive strategies. Males both provision and compete, and these behaviors are not necessarily mutually exclusive. It is important to emphasize the remarkable behavioral plasticity found in human males, when compared to other primates and other social mammals. This flexibility may emphasize competition and fast reproduction and indirect care-giving in many socioecologies. But the ability to provision (above as hunting, but also through other means) a slow-growing, costly human child has likely been a critical factor in the evolution of cooperation and modern human life history traits. Men, both competitors and providers, serve as first-line allomothers, even with a vast flexibility in their behavioral motivations.

Praha, Czech Republic

Synonyms

Male intra-sexual competition; Male–male contest

Definition

Direct or indirect competitive interactions over access to females, their gametes or resources to attract females.

Introduction

Male–male competition is, along with female choice, one of two main mechanisms of sexual selection (Darwin 1871; Andersson 1994). However, male–male competition has received much less theoretical and empirical interest than female mate choice, perhaps because it is conceptually more straightforward and easier to comprehend (Parker 2014). Competition among males that increases their fitness (reproductive success) is performed to increase an individual's access to females or their eggs. It is manifested before copulation (precopulatory male–male competition), between copulation and fertilization (postcopulatory male–male competition), or after fertilization. While it has long been believed that male–male competition and female choice are mutually reinforcing, research in recent decades suggests that it is often not the case.

Forms of Male-Male Competition

Traits that undergo sexual selection are sometimes divided between armaments (weapons used in male–male contests and signals of male fighting

ability – status badges) and ornaments (signaling traits used by females in mate choice decisions). However, many sexually selected traits have a dual function and are clearly affected by both forms of sexual selection (Andersson 1994). It appears that many sexually selected traits may have initially undergone selection in the context of male–male contests and then have subsequently been adopted by females as a signal of male quality. This is because male weapons are honest “signals” of male fighting ability since they are routinely put to trial during male contests. Such traits can then be reinforced through female choice, with both intra- and intersexual selection driving the evolution of the trait. The reverse process can also be true. Thus, traits traditionally viewed as ornaments that have been selected through female choice may be used by males in aggressive displays, including such traits as bright coloration and elaborated body appendages (Berglund et al. 1996).

The two mechanisms of sexual selection need not always be mutually reinforcing. Recent research documented that male–male competition and female choice can act in concert, independent of each other or in opposition. A common illustration of concerted evolution is male coloration. For example, red nuptial coloration in the male three-spined stickleback fish (*Gasterosteus aculeatus*) appears to be selected through male–male competition and female choice. Red coloration is a characteristic of dominant individuals that win fights, and females prefer to mate with redder males. Additionally, variation in redness increases under male–male competition and this may facilitate female choice (Candolin 2000). In contrast, conflicting selection pressures are involved in the production of social pheromones by males of the speckled cockroach (*Nauphoeta cinerea*), with differences in male–male competition and female attraction signaling optima. Hence, male cockroaches with a pheromone level that enables them to gain a dominant position are not preferred by females (Moore and Moore 1999).

The form of male–male competition varies widely among taxa and mating system. The most obvious is male–male interference competition. It is manifested as a physical contest (direct fight),

signaling contest (ritualized fight in which an individual matches themselves against an opponent via the expression or display of signal traits), or a combination of both. Most direct fights ensue when a signaling contest does not lead to a clear winner. For example, male African annual fishes (genus *Nothobranchius*) compete for access to females by rapidly approaching an opponent and performing lateral displays that involves spreading the unpaired fins. Males are brightly colored and coloration and body size usually determine the winner of the contest at the signaling stage. Lateral displays expose bright coloration and include tail beating, which directs a stream of water toward the opponent, and mutual threats performed with prominently displayed branchiostegal membranes (Passos et al. 2015). When the difference between males is small and the contest is not resolved with these displays, the contest escalates, with attempts to bite the opponent’s fins and flanks. If the contest is still not resolved, males may lock jaws, sometimes remaining in this position for several minutes (Polačik and Reichard 2009) and with potentially fatal consequences for one of the combatants.

Larger body size or body mass is perhaps the most obvious and probably most common trait that is selected through male–male interference competition. Body size is a good predictor of overall physical strength and performance (McCullough and Simmons 2016). In staged contests, larger males enjoy a substantial advantage, and body size/mass is often the clearest predictor of the outcome of a contest, though it is often correlated with other traits that may contribute to success.

Many direct male–male contests rely on the use of weaponry. Weapons such as horns, antlers, spurs, enlarged jaws and teeth, and other body structures and appendages are used to directly outcompete an opponent. At the same time, weapons often serve as a signal of fighting ability (badge of status) and are used during the signaling stage of a contest. Only when any of the rivals retreats from the signaling contest, a physical interference follows. For example, male red deer fight over possession of females with rivals wrestling with their antlers and attempting to push each

other away. Fights in other species may involve pushing, pulling, or dislodging an opponent. The size of weaponry is often associated with body size and both may be indicators of overall male condition (Andersson 1994). Fighting is costly and potentially lethal, and many contests are resolved at the signaling stage despite males possessing formidable weapons. In the case of red deer, rival males walk in parallel and assess the opponent's antlers and body size. It is only when neither male backs down from a contest that a fight with antlers occurs, potentially with serious injuries.

Other traits selected through male–male competition have a primarily signaling function. While they vary more widely than traits used in direct contests, they supposedly also indicate overall individual performance. Acoustic and visual displays are the best researched signaling traits, though chemical traits appear more common than generally assumed, and other modalities, such as electrical discharges in electric knife fishes (Gymnotiformes), are known to serve for signaling individual characteristics. The function of most signals in the context of male–male competition is intimidation. Hence, many such traits tend to be exaggerated. Yet, for a signal to be evolutionary stable, it must carry honest information about the status of the signaler: his physical strength, body size, condition or prior residence, and ownership of a breeding resource. For example, some aspects of the vocal signals of male red deer (minimum formant frequencies) are constrained by individual anatomical features, directly associated with male body size. Hence, it provides receivers with accurate information by which they can measure a rival's competitive ability (Reby and McComb 2003). Signaling male fighting ability, however, may also include subtler signals. Cuticles of most terrestrial arthropods contain cuticular hydrocarbons, semiochemicals with extensive within-species variation (Ingleby 2015). Cuticular hydrocarbons convey complex information about an individual, including information on male competitive ability. Indeed the composition of these chemical signals can have a profound influence on the outcome of male–male competition (Lane et al. 2016).

The expression of weapons and signal traits may be constrained by direct and indirect costs. First, direct costs arise from increased risk of damage or mortality. In the Asian rhinoceros beetle (*Trypoxylus dichotomus*), the risk of breakage is highest for the longest horns, and overly large horns may, therefore, constrain selection on the continued exaggeration of horn length driven by male–male competition by setting a mechanical limit on maximum horn size (McCullough 2014). Second, exaggerated signals of male–male competition ability may incur a cost of increased predation by reducing escape ability or increasing detectability by predators. In *T. dichotomus*, males with larger horns suffer significantly higher predation rates from avian and mammalian predators (Kojima et al. 2014). Likewise, many conspicuous signals of different modalities carry considerable survival costs by attracting enemies exploiting signal transmission such predators or parasitoids (Zuk and Kolluru 1998). Third, there are indirect costs that include energy depletion (allocation of resources to the trait expression traded off against its use in somatic maintenance, immunocompetence, or sperm production). Fourth, increased expression of factors within particular hormonal pathways that are functionally essential for the expression of the trait or signal can be costly for other phenotypic functions (Blagosklonny 2008). Hence, optimal trait expression to maximize lifetime fitness (reproductive success and survival) is often much lower than the maximum potential expression of the trait.

Lekking males compete for access to females via displays, aggregating in large numbers in specific spots visited by females. Lekking is relatively widespread among insect, fish, and bird species, but also recorded in other taxa such as mammals. Male–male competition on leks is severe, leading to high variance of male mating success. It is generally assumed that reproductive success of males in leks depends on female choice, but competition to obtain a display site on the lek and for the best positions within the lek also contributes to male success (DuVal and Kempenaers 2008). For example, in black grouse (*Lyrurus tetrix*), lekking males fight frequently

and successful males experience high success (Hämäläinen et al. 2012).

Endurance is an important, but often overlooked, aspect of male–male competition and describes the temporal component of male–male competition. To be successful, dominant males must maintain their high rank across a time span of days, weeks, months, or even years. The length of the breeding season varies widely among taxa, environments, and geographic regions. Highly seasonal environments often have a breeding season confined to a relatively short period when most fertilizations occur. In other taxa and less seasonal regions and environments, fertilizations may occur throughout the year. Male–male interference competition is typically highest when female receptivity is temporally clustered within a short period, and the most successful male may secure a large number of fertilizations. However, this scenario is also prone to the evolution of alternative mating behaviors when some males circumvent direct competition with the highest-ranked males and undermine their ability to control access to females. Dominant males typically cannot monopolize all females when they are unable to control their spatial distribution (Reichard et al. 2005).

Harems are examples of mating systems with low temporal clustering of female receptivity combined with an elevated importance of male–male competition for reproductive success. Possession of a harem is physiologically demanding and potentially costly to the territory holder through frequent contests with rival males. Harem holders (and alpha males in social groups with subordinate males) stage many contests from rivals for their position, and there may be substantial turnover of individual males in the possession of the top rank. Defense of harems increases immediate reproductive success (the number of progeny) but has longer-term consequences for survival and may lead to rapid reproductive senescence (Lemaître et al. 2014).

Mate guarding is another mechanism of male–male competition. In some taxa, males restrain female association with other males to ensure paternity of their offspring is not compromised. Males may simply remain in close proximity to a

female and attempt to repel any rivals. Sometimes, mate guarding involves prolonged or repeated mounting of a female, despite no further sperm transfer (Baxter et al. 2015). For example, in the bug *Lygaeus equestris*, pairs can remain in copula for over 15 h and regularly move and feed in this position, with males walking backward or being dragged along. Still, only a period of 1–2 h is needed for successful insemination (Alcock 1994), and the remaining time spent on copulation is probably a form of mate guarding that reduces the likelihood of female remating.

Scramble competition for access to females is a frequent, though relatively rarely examined, form of male–male competition. Successful searches for available females may considerably increase male fitness and imposes selection on superior sensory ability and locomotor organs. Hence, the most mobile males in a population can mate with more females, outcompeting less mobile males. In red-spotted newts (*Notophthalmus viridescens*), tail size is associated with locomotory capacity, and males with the largest tails have the greatest mating success, possibly due to higher ability to capture females (Able 1999). In many arthropods, males have larger eyes, antennae, and other sensory organs than females which have presumably evolved as an adaptation to locate mates, indirectly pointing toward the importance of scramble male–male competition. A temporal component is intrinsically important in scramble competition, and in many anurans (toads and frogs), males intercept females already on their way to a breeding pond and clasp them in amplexus to secure early access to females.

Male–male competition for reproductive success goes beyond direct interference, even at the premating stage. In many mating systems, some males can circumvent direct male–male competition by alternative mating behaviors (AMB). AMB are behavioral adaptations that enable males to compete with their rivals (and sometimes outcompete them) through the use of behavior that is different from the “typical” male–male interference competition. The most common examples are sneak copulations (in internally fertilizing species) or sneak fertilizations (in species with external fertilization). When sneaking, a male deceives

his rival and his access to a female is typically cryptic, at least until copulation/gamete release. Sneak male deception takes the form of camouflage of their external appearance (female-like appearance), hiding in a structured environment, or their combination. For example, in bluegill sunfish (*Lepomis macrochirus*), males may develop either into a territorial male that sexually matures at the age of 7 years and invests in territory defense, nest construction, female courtship, and parental care. Alternatively, males may mature when only 2 years old as a sneaker and compete with parental males (and other sneakers) for fertilization. Young sneaker males “streak” into the nest of a territorial male during female egg laying and may fertilize a subset of eggs before being chased away by the territorial male. Older sneaker males mimic female behavior and coloration and deceive territorial males into identifying them as a second female in the nest (Neff and Gross 2001).

A traditional view of male–male competition considers sneakers to be of low quality, incapable of winning contests and therefore making “the best of a bad job” to gain any reproductive success. However, there is now good evidence from several mating systems to suggest that females sometimes prefer to mate with sneaker males. By preferring sneaker males, females avoid limitation of the expression of their mating preferences by resource monopolization by males winning contests over breeding resources. This leads to an incongruence between male–male competition and female choice where female choice is affecting the final outcome of male–male competition (Reichard et al. 2007). In European bitterling fish (*Rhodeus amarus*), males defend territories with living freshwater mussels into which females deposit their eggs. A limited number of dominant males may control most oviposition sites, forcing females to lay the eggs in their territories, despite a mate choice preference for other males who have not acquired their own territory. Bitterling females sometimes actively engage in a conspicuous behavior that attracts sneaking males and increase the time window for the eggs to be fertilized (Smith and Reichard 2005), modifying the outcome of male–male competition when males are

of unequal competitive ability but when resource defense is crucial for breeding.

Alternative mating behavior may have a genetic basis, depending on the developmental stage or age, or may be entirely flexible and context dependent. In ruff (*Philomachus pugnax*), satellite males tend to steal copulations from dominant males and “faeder” males mimic females. Both alternative male forms differ conspicuously in behavior and coloration from dominant males and the forms are genetically determined. Each alternative male morph possesses a unique, non-recombining chromosomal inversion (Küpper et al. 2016). In many fish (and other) mating systems with breeding resource defense (i.e., nesting sites), males compete with other males by sneaking fertilizations when young and start to compete for breeding resources when they grow older and larger (Wootton and Smith 2015). Yet, in some of these cases, especially in short-living species, differences in body size among males are relatively small, and each male is capable of playing the role of territorial and sneak male, with switches between the tactics within seconds. In the European bitterling, individual males frequently switch between territorial and sneaking behavior, often in a time span of minutes. They attract females to their own breeding territory and, at the same time, attempt to sneak-fertilize the eggs of females laid in the territories of neighboring males (Reichard et al. 2004). In general, the success of alternative mating behavior is dependent on demography (ratio between males and females, population density, male morphs density), environmental conditions (habitat complexity and ability to hide), and the female response to alternative mating behavior (Reichard et al. 2007).

Finally, male–male competition may extend beyond fertilization. In the bluegill sunfish, territorial males care for the offspring for several days. Parental males in this species are often cuckolded by sneakers. However, they have the capacity to assess their paternity level using the visual presence of parasitic sneaker males during spawning and, in addition, using olfactory cues released from the offspring after the eggs hatched. Parental males dynamically adjust their parental care and

cannibalize those clutches for which their paternity share is low (Neff 2003). Another example of male–male competition after fertilization can be found in the three-spined stickleback. Male stickleback signaling effort (red body coloration) actually increases during the post-mating period when males fully engage in parental care and no new partners or fertilizations can be obtained. Parental care is exclusively paternal in this species, and male bright coloration may indicate his ability and motivation to defend the nest and offspring against competing intruders that might steal or cannibalize the nest (Candolin and Tukiainen 2015).

The relative importance of male–male competition for reproductive success arises from variation in resource investment, parental care, fertilization mode, and other parameters. In mating systems with no male contribution to post-fertilization reproductive effort, the largest or strongest males secure access to a large number of females in harems. In contrast, when high parental effort is needed for raising the offspring successfully, stable pairs are formed, and the importance of male–male competition for fertilization is low or restricted to postcopulatory processes. In mating systems with pair bonds, males may compete for the access to females with the highest reproductive value (i.e., fertility), though pairing in such systems is generally relatively unrestricted by mate coercion and dominated by female or mutual mate choice rather than direct male–male competition.

Conclusion

Male–male competition is a powerful mechanism of sexual selection that takes many different forms but is selected to secure access either directly to females (or their gametes) or to breeding resources critical for reproduction. It may be independent of female choice and postcopulatory processes, but often acts either in concert or in opposition to female choice. Interference competition involves direct physical or signaling contests between males, with development of weapons and expression of signals being constrained by direct and indirect costs associated

with their possession. Other forms of male–male competition include scramble competition for access to females, lekking, mate guarding, and alternative mating behaviors (e.g., sneak copulations or mimicking females) that circumvent direct contest with stronger males. Endurance is an important, but frequently neglected, aspect of male–male competition and recognizes that male success integrates over his lifetime. Male–male competition can extend beyond fertilization, and males may adjust the level of their parental care to perceived paternity.

Male-Provisioning Hypothesis

Siobhán M. Mattison

University of New Mexico, Albuquerque, NM, USA

Synonyms

Food sharing hypothesis; Hunting hypothesis

Definition

The Male Provisioning Hypothesis (MPH) proposes that men have evolved to provision their

mates and children and that this provisioning has resulted in significant changes to the evolution of human biology and life history.

Introduction

Although the MPH has had many proponents, there have also been many detractors. This article reviews the theoretical underpinnings of the MPH and contrasts the hypothesis with commonly cited alternatives. In reviewing the evidence brought to bear on these alternatives, the article concludes that although male subsistence and provisioning efforts are significantly greater in humans compared to other mammals, the MPH is nonetheless insufficient as a sole explanation for the evolution of humans' extended life histories and attendant adaptations. Rather, men's investments in their children and wider communities are flexibly allocated. Human adaptations are more likely the result of a system of cooperative breeding in which any of a variety of possible caretakers subsidizes a lengthy and expensive period of child-rearing.

Provisioning Does Not Require Hunting and Hunting Does Not Require Provisioning

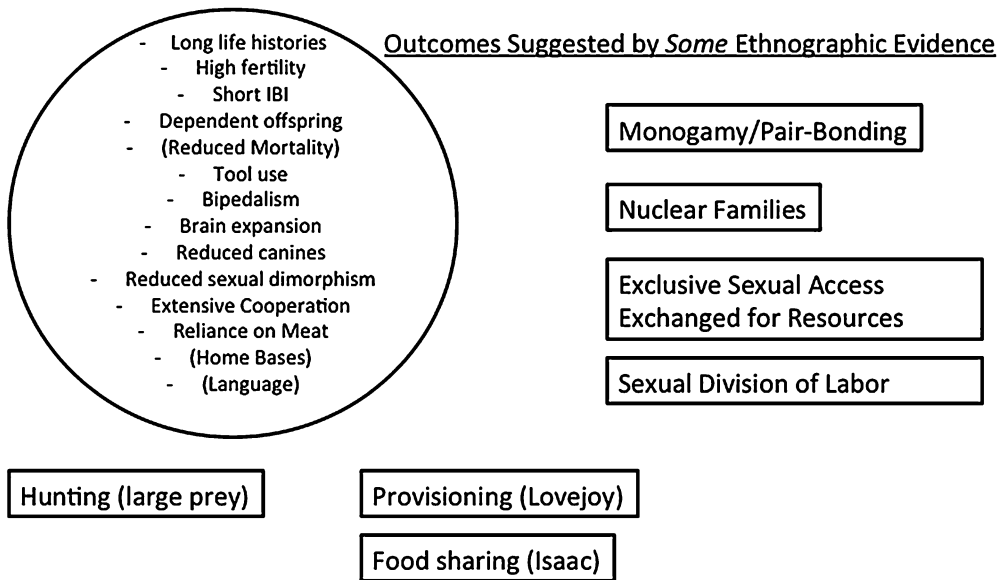

The origins of the MPH reside in part in the observation that the human diet consists of a relatively high proportion of meat (Fig. 1). Indeed, although variable, meat contributes significantly more to the human diet in comparison to the diet of our closest living relatives (Hill 1982). Paleoarchaeological evidence initially suggested that meat consumption became significant concurrently with a number of changes in human life history and biology that are central components of the modern human adaptive complex, including bipedalism, tool use, reduced canine tooth size, decreased sexual dimorphism, extended life histories, higher fertility, lower interbirth intervals, increasingly dependent offspring, and increased cooperation (Isaac 1978; Lovejoy 1981) (Fig. 2).

The MPH links together these features in an evolutionary scenario involving: (1) a sexual division of labor in which men primarily acquired meat and women primarily focused on gathering;

Male-Provisioning Hypothesis,
Fig. 1 Percentage of calories derived from meat among a sample of mammals, nonhuman primates, and human forager groups (Selected data drawn from Hill 1982)

Outcomes Suggested by Paleontological/Archaeological Evidence

Male-Provisioning Hypothesis, Fig. 2 A visual model of the Male Provisioning Hypothesis (MPH). Male provisioning, whether via hunting or food sharing, is thought to be a key driver in the origins and maintenance of the human adaptive suite as depicted by the paleontological and archaeological record, shown in the *circle* on the *left*

(items in parentheses are less commonly emphasized outcomes). Ethnographic evidence that has been used to bolster the case for the MPH is shown on the *right*. As discussed in the text, human families are more variable than viewed in this depiction, undermining some of the key premises of the MPH

M

(2) meat being used by men to provision their mates and biological offspring; (3) a “sex contract” (ibid.) by which women traded fertility for meat; leading to (4) monogamous unions and the establishment of the nuclear family (i.e., a man, his mate, and their dependent offspring) as the elementary human family form. Note that as stated here, the MPH does not require hunting, per se. In fact, in one of the earliest statements of the MPH, Isaac (1978) was careful to distinguish provisioning from hunting, indicating that meat was more likely to have been scavenged than hunted when proto-hominin males began provisioning their mates.

Nevertheless, the MPH has more often been associated with hunting than not (Dart 1953; Gurven and Hill 2009; Gurven and von Rueden 2006; Hill 1982; Kaplan, Hill, Lancaster, and Hurtado 2000; Washburn and Lancaster 1968). Indeed, although the term “male provisioning hypothesis” can be most closely attributed to Owen Lovejoy (1981), the model has its origins

in various versions of the “hunting hypothesis” (HH) dating back at least to Westermarck (Westermarck 1903, cited in Kristen Hawkes 2004) and elaborated most influentially by Sherwood Washburn (Hawkes 2004). Washburn’s (Washburn and Lancaster 1968) original arguments foreshadow modern depictions of the MPH: in his view, hunting evolved alongside bipedalism and tool use, and with bigger brains, which reflected the increased skill associated with hunting as opposed to other forms of foraging. Larger brains would have necessitated the birth of immature offspring to avoid taxing the maternal pelvis. This, in turn, led to increased dependency of offspring on their mother and resulted in the need for male provisioning.

Following evidence that bipedalism, brain expansion, and big-game hunting are separated in the paleoarchaeological record by millions of years (Klein 2009), modern variants of the MPH have shifted emphasis away from the broader linkages envisioned by Washburn and others and

toward its effects on the human life history, *per se*. In the most influential version of this argument, Kaplan and colleagues (Kaplan et al. 2000) have proposed that hunting allows for increased investment into “embodied capital” (i.e., skills, knowledge, health), which is accrued during a lengthy period of juvenile dependency, and pays off when skills-intensive foraging (i.e., hunting) increases the reproductive rate of provisioned females. In this view, male provisioning via hunting is the key to underwriting relatively rapid reproduction among human females, as mothers devote the surplus energy to reproduction and childcare rather than foraging (see also Lovejoy 1981). Females offer fidelity to men in exchange and pair-bonds (Gurven and Hill 2009) and nuclear families result (see also Lancaster and Lancaster 1983, 1987; Lovejoy 1981).

Although the MPH and HH are closely related and share certain features in common, it is important to distinguish between them for at least two reasons. First, male provisioning via hunting presumably requires more skill (if not risk) than scavenging or other forms of provisioning and therefore places a stronger emphasis on men’s increased capabilities as being ultimately responsible for shifts in human life histories. As discussed more fully below, this hypothesis continues to inspire debate over the extent to which hunting functions as a means of provisioning hunters’ families (Gurven and Hill 2009; Wood and Marlowe 2014) or whether it serves more commonly to signal status and high quality to nonkin (Bliege Bird and Bird 2008; Kristen Hawkes et al. 2014). Second, male provisioning, whether or not via hunting, *is* one means by which human allomothers contribute to childrearing. Delineating the factors that predict when and how men invest in children may be more fruitful to our understanding of the origins and maintenance of human life histories than a more narrow focus on hunting, *per se*.

Controversy/Alternative Views

The male provisioning hypothesis has been at the center of one of the most enduring recent debates in evolutionary anthropology. Although this debate

takes different forms, the heart of it concerns (i) the relative contributions to subsistence by males and females and (ii) other possible motivations for male hunting. These two issues have different implications for understanding more generally how men contribute to the evolution of human life history. Undermining the significance of provisioning as a motive for hunting need not imply that men do not or have not in the past chosen to provision their mates. Nor does it need to imply that hunting has lacked an impact on the human life history; even if meat was not used as a form of direct provisioning and was instead widely shared, it would still have been associated with increased energy that could be allocated by women to reproduction instead of foraging (Kaplan et al. 2000; Marlowe 2000). On the other hand, if hunting is not primarily a means of provisioning mates, then pair-bonding and nuclear families do not automatically follow. Moreover, if females are able to supply most of the calories they need in order to subsist, then the degree to which hunting adds to energy reserves is called into question.

Kristen Hawkes (2004) has been perhaps the most vocal critic of the MPH and has provided evidence that supports (i) a stronger role for women in contributing to the diet of hunter-gatherers; and (ii) more self-centered motivations for male hunting than a provisioning model would imply. With respect to (i), evidence suggests that there is more overlap in men’s and women’s subsistence strategies in foraging societies than previously recognized (e.g., Bliege Bird and Bird 2008). This finding is bolstered by cross-cultural evidence of female self-sufficiency in the absence of male support (e.g., Brown 1970; Quinlan and Flinn 2005) and by quantitative evidence of more consistent returns from female rather than male foraging efforts in contemporary hunter-gatherer populations (Bliege Bird and Bird 2008). All of this is not to say that men’s hunting provides negligible dietary input – men contribute as much as 65 % of the calories and 85 % of the protein in forager diets (Cordain et al. 2000; Kaplan et al. 2000) – but it does speak to a more nuanced and flexible system of subsistence than typically advocated by the MPH.

With respect to point (ii), Hawkes and colleagues continue to argue that men’s hunting

targets large game that is both widely shared and unpredictably acquired and therefore that men hunt as a means of “showing off” rather than as a form of provisioning (Hawkes and Bliege Bird 2002; Hawkes 1991; Hawkes et al. 2014). In this view, hunting serves as a costly signal that attracts potential mates and allies to good hunters. Meat is not provisioned, but is instead a publicly shared good. Men benefit reproductively from being good hunters, not by investing directly in their wives and children, but by acquiring more or higher-quality mates and allies. Hungry foragers make for an eager audience and the women who contribute to good hunters’ reproductive success also stand to gain, albeit indirectly (e.g., genetically).

Proponents of the show-off model have furnished a variety of evidence in support of its main predictions, including direct evidence that hunters’ wives and children do not receive more shares of hunted meat than do other foragers and by indirect evidence that pair-bond stability is more sensitive to the intensity of male mating competition than by “father effects” related to provisioning (Blurton Jones et al. 2000). Still, data have also supported increased provisioning during critical periods (e.g., lactation) when women are at reduced capacity to meet their own needs (Marlowe 2003) and contradictory interpretations of hunting data from the same society (Kristen Hawkes et al. 2014; Wood and Marlowe 2014), confound resolution. Solving these empirical conflicts will require more data and clarification of the sources of variability in meat apportionment across hunter-gatherer societies. Regardless, the benefits to females of bonding with males are more than just dietary (Scelza 2013), and human males invest significantly in their offspring in a wide variety of contexts (Gray and Anderson 2010), suggesting that these views are not mutually exclusive.

Determinants of Male Parental Investment

Challenges to the hunting hypothesis and earlier iterations of the MPH are sometimes depicted as a more general challenge to the importance of male provisioning in human family systems, but this

should not be so. Although the degree to which men help is variable across cultures and less consistent than maternal investment, it is nonetheless significant in relation to the majority of nonhuman primates (Hill 1982 and Fig. 1). Several hypotheses explain when and how intensively men invest in their children, and a wide body of empirical literature has tested these hypotheses (see Gray and Anderson 2010 for review). These tests indicate that fathers invest frequently and significantly under a wide variety of circumstances and even in cultures where the significance of their role is downplayed (Mattison et al. 2014). It is also clear that the means of caring for their children extend far beyond provisioning, including both direct and indirect care (Marlowe 2000) and in relation to the support provided by other caretakers (Gurven and Hill 2009; Kokko and Jennions 2008; Marlowe 2003). Critically, however, the support that fathers provide is sensitive to the subsistence base (Hewlett 1988; Mattison et al. 2014), such that it would be unwise to extend the relationship between paternal investment, monogamy, and nuclear families seen in many contemporary Western societies back into a proto-hominin past.

Conclusion

... ‘natural’ parental behavior is often surprisingly flexible, and there are multiple pathways to successful parenting. (Sear 2016, p. 101)

The Male Provisioning Hypothesis in its most virile form has more or less been laid to rest – that is to say, it is no longer generally accepted that men’s hunting alone can explain the adaptive suite that separates humans from nonhuman primates. The current debate centers instead on the relative contributions of fathers, grandmothers, and other kin to the origins and maintenance of our extended life history and relatively rapid reproduction. Whereas it is undeniable that paternal investments in different forms of care (both direct and indirect) underwrite these costs in societies when men benefit reproductively from doing so, it is equally clear that many other care-takers are often as, or more, important (Sear and Mace 2008).

At the same time, the significance of men's hunting in human evolution is not in doubt. It is now "...largely accepted that successful hunters (1) contribute valuable protein and fats to the diet, (2) gain prestige and social status, and (3) tend to have higher reproductive success than poor hunters" (Gurven and von Rueden 2006, p. 81). In light of the available evidence, it seems likely that hunting involves a variety of functions of which provisioning is only one (see Gurven and Hill 2009). This does not diminish the importance of hunted meat as a source of nutrients for hunter-gatherers, but it would seem to weaken the link between hunting, monogamy, and nuclear family formation.

The MPH and the HH, if questionable in their specifics, have nonetheless been useful frameworks to understand how the support of different caretakers might affect the evolution of human life histories. Indeed, the recognition that provisioning and cooperation have played central roles in extending our life history has led to sophisticated applications of the cooperative breeding hypothesis to understand how various care-providers navigate the costs and benefits of providing care under different circumstances (Sear 2016). And unlike the MPH and HH, the cooperative breeding hypothesis implies nothing about universals in the sexual division of labor or the importance of specific caretakers. Rather, it emphasizes our vast flexibility in caring for our unusually dependent offspring.

Exponential growth; Malthusian growth

Definition

An Essay on the Principle of Population by Thomas Robert Malthus (1798) is a book widely viewed as having profound impact on the biological and social sciences by recognizing basic biophysical, demographic, and economic principles that can lead to population growth and possible collapse.

Introduction

Be fruitful and multiply. Fill the earth and govern it. Reign over the fish in the sea, the birds in the sky, and all the animals that scurry along the ground. – Genesis 1:28

The power of population is indefinitely greater than the power in the earth to produce subsistence. – Malthus 1798

An Essay on the Principle of Population by the Reverend, Political Economist, and Demographer, Thomas Robert Malthus (1766–1834), is perhaps the most important document ever published on population, yet its central thesis continues to be highly controversial between natural and social scientists today. First published anonymously during the Enlightenment in 1798, the subsequent five editions bearing Malthus' name (the last in 1826) refined and elaborated on initial arguments, as well as responded to critics with data, case studies, and mathematical and logical proofs. More than 220 years after the first edition, the arguments and counterarguments provoked by *An Essay on Population* (as it became popularly known) are still central to discussions of future human and planetary wellbeing today. In this chapter I (i) introduce the historical context and setting in which Malthus wrote the book, and (ii) provide a brief overview of the *Essay's* general concepts and content, and (iii) conclude with a summary of the enduring legacy of Malthus' *Essay* in modern science and society.

Historical Context

Thomas Robert Malthus was born in 1766 in Surrey outside of London. He studied in Jesus College at Cambridge University where he was later elected Fellow. Malthus was Professor of History and Political Economy for the East India Company College in Hertfordshire. He became ordained by the Church of England in 1788 and was elected Fellow of the Royal Society in 1818. An interdisciplinary scholar, he influenced a vast range of study including theology, biology, demography, public policy, economics, agriculture, labor, commerce, and moral philosophy.

Malthus was educated during the enlightenment when there was much optimism for the recent human progress. During this time, the arrogant view of humans as superior beings on Earth contributed to the growing enlightenment prescriptions for increased fertility, because population increase and economic growth were so intimately coupled. During this time, Adam Smith's *Wealth of Nations* was well received and

paved a path for prosperity through the “invisible hand” of free markets. Malthus was a skeptic of the idea that increasing revenue and wealth would benefit all, citing that a substantial proportion of the population in all societies is in poverty. Malthus' *Essay on Population* was specifically critical of recent utopian views set forth by Marquis (a.k.a. Nicolas) de Condorcet in France and Briton William Godwin's writings on “the perfectibility of society.” The French Revolution, which largely stemmed from the rising disparity between the leisure and working classes, spurred debates among the British aristocratic circles. The inseparable political and religious establishments in Britain were trying to prevent the revolutionary contagion, as they saw it, from spreading across the English Channel.

The first edition of Malthus' *Essay* laid out his thoughts and rebuttals to these scholars. It begins with a conversation with “a friend” who turns out to be Malthus' father regarding the speculations on the “future improvement of society” and “perfectibility of man” written by Godwin, Condorcet, Smith, David Hume, and others of the time. Malthus was an empiricist who held that “*acknowledged truth in philosophy is that a just theory will always be confirmed by experiment.*” The second edition provided expanded discussion and data. For example, Malthus cites Benjamin Franklin's observation that the New World colonies of the Americas had a population doubling time of every 25 years (Franklin 1751). In contrast to the Eurocentric focus of much of the discussion on population and society at the time, Malthus' work was global in scope, involving case studies and data from societies spanning the Far East and Pacific Islands as well as the Americas (Bashford and Chaplin 2016).

Malthus' Theory and Implications

Malthus' central thesis addressed the relative rates of food production and population growth, observing that, because human population grew exponentially (geometrically 1, 2, 4, 8, 16, 32, 64, etc.) and food production arithmetically (e.g., linearly 1, 2, 3, 4, 5, 6, 7, etc.), sooner or later

Malthus on Population,

Fig. 1 illustrates Malthus' theory. Over time population growth increases exponentially if unchecked. In contrast, resource production grows linearly. At some future time, growth in population will exceed the supply of resources – known as the “Malthusian Catastrophe” – and the population collapses back to subsistence levels

human population would outstrip resources (Fig. 1). Gains in living standards would be short-lived, and populations would collapse to subsistence levels. This was based on two assumptions that Malthus thought were innate and incontrovertible. First, food is necessary for humans to live. Everyone requires about 2000 calories per day and a healthy balance of fats, proteins, and carbohydrates. Second, the passionate drive between the sexes to procreate and “*be fruitful and multiply*,” will inevitably lead to the birth of more kids and population growth. Malthus predicted that checks on population would come in two forms: *positive checks* that raise the death rate such as widespread “famine, pestilence, and war” and *preventative checks* that lower the birth rate including moral restraints such as birth control, postponing marriage, and celibacy. Infinite growth in population, Malthus proclaimed, is impossible due to finite limits of the Earth.

Malthus' Iron Law of Wages provided one of the earliest economic insights into the biophysical constraints that couple human population to the natural environment. It suggested that growing populations would result in a surplus of laborers, which in turn would drive down wages towards poverty levels. Moreover, increasing population and demand for commodities would drive up the price of provisions, while simultaneously decreasing wages, leading to poverty and misery among the working class. Thus, according to Malthus, in the long-term there will always be poor in all societies. Population growth would exacerbate the problem. Malthus writes that life for the poor would be so miserable “*Even when they have an*

opportunity of saving they seldom exercise it, but all that is beyond their present necessities goes, generally speaking, to the ale-house” (p. 35).

Influence on Biology: First Law of Nature

Malthus had a profound influence on the fundamental demographic models that are still used to study humans and the millions of other plants, animal, and microbe species on the planet today. It was perhaps unforeseen by Malthus that his *Essay* would revolutionize biology. His observation that all living organisms have the capacity to produce more offspring than can survive was a cornerstone in the development of evolutionary biology. All populations that are unchecked, including humans, have the intrinsic capacity to grow exponentially.

The implications of Malthus' theory can be formulated mathematically, where the population growth rate (r) is equal to births (b) minus deaths (d) plus immigration (i) minus emigration (e). So, a

$$\text{Population } (P) \text{ at steady state } = P = 0 = r = b - d + i - e. \quad (1)$$

At the global scale, we can assume net migration of zero and Malthus' theory can be expressed as an exponential function of the form,

$$P(t) = P_0 e^{rt}. \quad (2)$$

where $P_0 = P(0)$ is the initial population size, r = the population growth rate, and t = time. Therefore, all stable populations of all species have an

$r = 0$, on average and over the long-term, where births are equal to death rates, and i immigration offsets e emigration. A positive growth rate ($r > 0$) is exponentially. Such species would inevitably fill up the planet, exhaust all resources, and collapse to a steady state population. Conversely, populations with a negative growth rate ($r < 0$) are not sustaining and will inevitably go extinct. Critical for evolutionary theory, is that when populations are in steady state and $r = 0$, most offspring do not survive, selecting for the “fittest” individuals.

Malthus’ law of exponential growth is regarded as the first principle of population dynamics (Turchin 2003). Malthus’ conjecture that all populations have the intrinsic capacity to produce more offspring than can survive, and thus grow populations indefinitely if unchecked, had a profound impact on modern biology as evident by its inclusion in many introductory textbooks spanning the physical, biological, and social sciences today. Despite few scientific laws in biology, and

even fewer in the social sciences, Malthus’ observation on population is even considered a “law of nature” similar to Newton’s laws (Ginzberg 1986) which preceded Malthus in the *Scientific Revolution* (Fig. 2). In fact, Malthus wrote in *An Essay* about the influence of Newton’s *Principia* on his thinking of the fundamental biophysical laws that act on population. In turn, Malthus’ sixth edition published in 1826 had a profound influence on the formulation of evolutionary theory. In Charles Darwin’s *Autobiography* (p. 120) he writes:

I happened to read for amusement Malthus on Population, and being well prepared to appreciate the struggle for existence which everywhere goes on from long-continued observation of the habits of animals and plants, it at once struck me that under these circumstances favourable variations would tend to be preserved, and unfavourable ones to be destroyed. The result of this would be the formation of new species. (Barlow 1958)

Similarly, Wallace in 1905 in his autobiography *My Life* he wrote:

Malthus on Population, Fig. 2 shows growth in per capita energy consumption, population, and global energy consumption over time reproduced with permission from Schramski et al. (2019). Superimposed are some key publications that influenced or were influenced by Malthus’ *Essay*. The world’s population was about 800 million in 1798 when

Malthus first published the *Essay*. Today there are 7.7 billion people and rising. For much of this time population was growing faster than per capita and total energy consumption. However, around 1960 total energy use began to increase even faster than population. This energy is finite and largely in the form of fossil fuels (about 85%)

Perhaps the most important book I read was Malthus' *Essay on Population*. . . It was the first great work I had yet read treating any of the problems of philosophical biology, and its main principles remained with me as a permanent possession, and twenty years later gave me the long-sought clue to the effective agent in the evolution of organic species. (Wallace 1905: 232)

Equal Fitness Paradigm

In contemporary ecology and evolution, Malthus' first law of nature is a cornerstone of the Equal Fitness Paradigm (EFP; Van Valen 1973; Brown et al. 2018; Burger et al. 2019a). The EFP posits that, over evolutionary time, each parent must exactly be replaced by one offspring, birth rates must equal death rates, and this results in steady-state populations and equal fitness among all species. This is evident by the mere coexistence of the millions of species on Earth. Some fish, plants, and invertebrates produce literally millions of offspring and other species such as birds and mammals, produce very few. Yet, underlying all the enormous diversity of life on Earth are general life history laws: (1) demographic: regardless of the number of offspring produced in a lifetime, on average only two survive to replace the parents (in a sexually reproducing species) resulting in a steady-state equilibrium or non-growing population, and (2) mass-energy balance: each individual exactly replaces themselves in energy and material content, so a mass-energy balance must occur over a generation (Burger et al. 2019a). Thus, despite the enormous variation in biodiversity spanning many orders of magnitude in body size, generation time, and fecundity, all species are equally fit because ultimately each adult is exactly replaced by one surviving offspring that lives to reproduce. The EFP provides a null hypothesis and benchmark to understand the unique circumstances that has allowed the human species to maintain positive population growth. These are just some of the profound insights inspired by Malthus' *Essay*. It still influences modern biology today and can play a pivotal role in extending fundamental evolutionary and demographic theories to understanding the origins of the Anthropocene – the age of global human ecological dominance.

Malthus' Influence on Society

It was evident from the first edition of Malthus' *Essay* that it would have a profound impact on society, influencing the first English census of 1801, and the Poor Law Amendment Act of 1834 which cut subsidies to the poor. Some interpretations of Malthus' work have presumably influenced political ideologies such as genocide and eugenics (Shermer 2016). A number of moral philosophers and historians painted Malthus as being insensitive to slavery, indigenous peoples, and the poor. Yet, in later editions of the *Essay*, Malthus does advocate for educational and economic policy interventions to mitigate the amount of suffering by the poor (Bashford and Chaplin 2016). He further writes about indigenous rights to their native lands, although he was rather vague about how to mitigate imperialism and exploitation of native peoples (Hodgson 2016). Nonetheless, in retrospect Malthus is often considered a forerunner of social Darwinism (e.g., Shermer 2016) because he applied fundamental laws of biology to human populations. However, the naturalistic fallacy instructs that just because things are so, doesn't mean they ought to be.

"Neo-Malthusians" Versus "Cornucopians"

The 1960s witnessed a resurgence of Neo-Malthusian campaigns for Zero Population Growth (ZPG) culminating with the publication of *The Population Bomb* (Ehrlich 1968), written by Paul (and Ann (The editor of *Population Bomb* insisted that Paul Ehrlich be the sole author when Paul and Ann Ehrlich coauthored the book)) Ehrlich, and the *Limits to Growth* (Meadows et al. 1972) report published by the Club of Rome written by a team of scientists lead by Donella and Dennis Meadows at the Massachusetts Institute of Technology. In response, Cornucopians (after the ancient Greek "horn of plenty") have argued against Neo-Malthusians, citing that technological innovations including energy efficiency, health and medical advancements, genetically modified crop breeding, petrochemical fertilizers,

mechanized agriculture, and irrigation have allowed resource supply to outpace growing population demand. Cornucopians extend Adam Smith's "invisible hand" of the free market to believing that supply, demand, and monetary incentives will continue to provide technology that will innovate our way out of environmental problems. This Cornucopian view shared by many neoclassical economists and technologists assumes that growth in the human system (population and economy) can continue indefinitely. In contrast, Jared Diamond's famous book *Collapse* (2005) is critical of Simon and the Cornucopians, stating that their assumptions were not in line with natural limitations.

Perhaps the pinnacle of this discussion culminated with a bet between, Paul Ehrlich (and others), and the American economist and Cornucopian, Julian Simon. Simon argued in the 1970s that we had already accumulated the knowledge required to supply the world's growing population for the next seven billion years (Simon 1981). The business professor Simon challenged the ecologist Ehrlich to choose any raw material and future date and Simon wagered that the real inflation-adjusted prices would decrease because of technology, rising standards of living, and free markets incentives that would drive the prices down (Simon 1980). Ehrlich took the bet arguing that rising demand from population and affluence would result in resource shortages, thus driving up prices. In 1980, in what has become known as the "Simon-Ehrlich wager" Ehrlich chose copper, chromium, nickel, tin, and tungsten with the predicted payoff date a decade later. Ehrlich lost the bet. The prices of all five metals declined during the 1980s. However, the prices of those commodities subsequently increased and other metrics of human well-being (e.g., numbers in poverty, income inequality, and pollution) have gotten worse. So, it is not that straightforward if Ehrlich or Simon was right (Sabin 2013). This debate between Malthusians and Cornucopians continues today (Fig. 3) and has motivated cross-disciplinary research seeking to explain the peculiarity of human population growth. Combining both the Malthusian and Cornucopian perspectives has led to quantitative models that

Malthus on Population, Fig. 3 shows climate protestor Brian Maitner holds a sign "MALTHUS WAS RIGHT" featuring Eq. 2 in El Presido Park in Tucson, Arizona, September 20, 2019, demonstrating the legacy of Malthus' seminal *Essay on Population*. Photo credited to Rachel Gallery

incorporate how population growth, interacting with biophysical resource constraints, can lead to biological and/or cultural innovations that allow humans to temporarily circumvent environmental constraints and continue growing (e.g., Boserup 1965; Nekola et al. 2013; Burger et al. 2017; Weinberger et al. 2017; Burger 2018). While these models shed light on how innovations have allowed exponential population growth, indefinite growth in a finite space is impossible and this was central to Malthus' thesis.

Malthus, Darwin, and Boserup

So far, the ascending spiral of positive feedbacks between population growth, innovation, and resource supply has kept pace with growing population and consumption levels (Fig. 4). How have humans been able to continue harnessing

Malthus on Population, Fig. 4 (a) Global human population over the past 10,000 years and some major innovations in human history that have contributed to increasing carrying capacity (Adapted from Nekola et al. 2013). Human population has increased from less than 1 billion before 1800, to ~2 billion in 1927, ~3 billion in 1959, ~6 billion in 1999, ~7 billion in 2011, to the now 7.7 billion on the planet in 2019 and is still increasing. (b) A conceptual model of how growth in the human system (population and economy) is characterized by positive

feedbacks between cumulative cultural evolution, technological innovation, and increased flow of natural and ecosystem services from the environment (adapted from Burger 2018). Cumulative cultural evolution is broadly defined as the accumulated socially learned knowledge and technologies that are tried, tested, recorded, transferred, modified, and recombined over time through social processes like copying, emulating, teaching, and learning. Malthus argued that these exponential processes cannot continue indefinitely on a finite planet

M

additional energy sources to temporarily escape checks on populations that seemingly constrain all other species? The Darwinian process of innovation and adaptation has allowed us to continually push environmental limits (Nekola et al. 2013). Thus, Darwinian innovations have allowed birth rates to far exceed death rates resulting in exponential population growth. However, the Malthusian process is that all species have the intrinsic capacity to increase population exponentially until environmental limits are reached. Research at the intersection of evolution and sociology has begun to investigate the role of cultural evolution in accelerating information exchange and innovations leading to continued exponential growth (Fig. 4).

The human ability to innovate and appropriate an ever-increasing resource supply has increased global carrying capacity to current exponential growth rates (Fig. 4). The French and Danish Agricultural Economist Ester Boserup acknowledged

the need to continuously innovate as population growth demands ever increasing resources (1965). As the human population grows, the demand for more resources has led to increased land intensification and higher crop yields culminating in the Green Revolution of the 1950s and 1960s that drastically increased crop yields worldwide. However, the study of complex societies has revealed diminishing marginal returns to growth (Tainter 2011, Strumsky et al. 2010; Diamond 2005) including a global decline of per capita consumption of several important global resources such as oil, phosphate, wood, wild fisheries, agricultural land, and freshwater (Burger et al. 2012). Moreover, the fraction of income spent on food and energy has been increasing since the late 1990s (King 2015). So, the scope for innovation to continue to stave off collapse as we reach planetary limits is an open question (Weinberger et al. 2017; Burger et al. 2017; Burger 2018).

Conclusion

Malthus' *Essay* has had an enduring impact on the natural and social sciences. Its principles continue to influence fundamental models in evolution, ecology, and human demography today. Its central thesis also continues to be a point of contention among Neo-Malthusians and Cornucopians. I end with three concluding points: (i) current population trends, (ii) Malthus' argument for the (im) perfectibility of humans, and (iii) Malthus' solutions and alternatives to the growth paradigm.

Current Population Trajectories

The global population was ~800 million people when Malthus wrote the first edition of *An Essay*. Today there are 7.7 billion people on the planet. There is much optimism that world population will reach a steady state and possibly even begin to shrink by the end of the century due to the demographic transition where the global population growth rate slows as fertility and mortality rates drop as countries urbanize and develop economically (Bricker and Ibbitson 2019; see also Burger 2019). However, per capita resource use and meat consumption (Schramski et al. 2019) increase with shifts in employment from resource-based rural economies to service and technology-based cities (Burger et al. 2019b). Moreover, decreasing fertility rates coincide with increasing per capita energy use across countries and within countries over time (Moses and Brown 2003; DeLong et al. 2010). The increased urbanization that coincides with economic growth, technological innovation, and higher standards of living are fueled largely by nonrenewable fossil fuels. About 85% of the global energy demand is still from fossil fuels despite campaigns and policies to transition to renewables. It is important to note that since 1960 per capita energy use has begun to increase faster than population (Fig. 2), exacerbating climate change. Malthus' *Essay* influenced Jevon's paradox, which states that increasing efficiency has unintended consequences of actually increasing the absolute amount of resource used, accelerating the drawdown of the planet's energy reserves (Jevon 1865).

The (Im)Perfectibility of Humans

Particularly interesting is the timing of Malthus' book in relation to the *industrial revolution* (Fig. 2), when humans began to exploit vast quantities of fossil fuel resources to power mechanized industries including agriculture, manufacturing, and transportation. Malthus' *Essay* does acknowledge technological improvements as a result of human innovations. He merely states the absurdities in thinking that increasing "perfectibility" could happen indefinitely. Malthus pointed out that there are fundamental limits to improvements. For example, he writes that "*One of the most obvious features of improvement is the increase of size. The flower has grown gradually larger by cultivation. If the progress were really unlimited it might be increased ad infinitum, but this is so gross an absurdity that we may be quite sure that among plants as well as among animals there is a limit to improvement, though we do not exactly know where it is.*" (p. 51).

In Malthus' critique of Condorcet's "Perfectibility of mankind" he writes "...*the mortality of man on earth seems to be as completely established, and exactly upon the same grounds, as any one, the most constant, of the laws of nature*" (p. 74). "*I think we may conclude, that we have rather less reason for supposing that the life of man may be indefinitely prolonged, than that trees may be made to grow indefinitely high, or potatoes indefinitely large*" (p. 77). The notion that indefinite growth is impossible on a finite planet has inspired philosophical discussions on alternative pathways for human societies.

Alternatives to the Growth Paradigm

In addition to being critical of the growth paradigm, Malthus' did provide solutions. He proposed that we need to change the "very nature of man?" taking *Preventative* checks to avoid population growth and collapse. To this end, Malthus inspired the pioneering works at the intersection of ecology and economics by Kenneth Boulding, Nicholas Georgescu-Roegen, Herman Daly, Howard T Odum, Vaclav Smil, Charlie Hall, Ken Klitgaard, and others who have advanced transdisciplinary research in the fields of ecological economics and biophysical economics. These

fields set themselves apart from neoclassical economics by placing the human population and economic system as a subsystem embedded within the global biosphere (Fig. 4) instead of being divorced from the natural environment. Malthus doesn't make any specific predictions of the timing of collapse. The central legacy of Malthus' *Essay* is the appreciation that growth cannot occur forever in a finite world. Accordingly, Malthus would argue that the growth paradigm that prevails in neoclassical economics today will ultimately fail. Appreciation of the fundamental biophysical constraints to growth is necessary to develop alternative pathways for sustaining the human enterprise.

The evolution of the mammalian ear and the comparative research with the ears of humans.

Introduction

In order to understand the evolution of the human ear, we must trace its origins and comparison in the mammalian lineage. Therefore, to identify the changes in the hearing capacity of the evolution of humans, a comparison had to be made to the evolution of other mammals (Masterton et al. 1968). It was concluded that high frequency hearing (>32 kHz) is a trait that characterizes mammals. This was due to the short distance of their ears, and the result for the selective pressure to know the accurate source of brief sounds. Sounds with a low frequency (<1 kHz) is a trait that characterizes all mammals, especially humans (Masterton et al. 1968).

The Eutherian Mammalian Ear

Regarding the evolution of the eutherian mammalian ear, Manley (2017) distinguished that during the Paleozoic era (>250 million years ago), the synapsids were no longer under the stem reptiles, forming mammal's ancestors. During the early Mesozoic era, the mammalian ancestors had a short-term middle ear connected to the lower jaw, which was later developed to a more distinct middle ear. The organ of Corti was adopted during this period. The integration of the bone into the

cochlea happened exclusively in therian mammals and took place prior to the cochlear coiling and the split of Eutheria from the Metatheria. The cochlear coil had as a result for the lagenar macula to be eliminated, leading to the evolution of prestins, a motor protein found in abundance in the lateral cell membranes of outer hair cells.

Motor Protein Prestin

This protein lead to a heightened sensitivity in low sound frequencies (see Dallos 2008; Li et al. 2010; Zheng et al. 2000, 2002) and works as a mediator between the somatic electromotility in the outer hair cells of the cochlea. These hair cells are in control for cochlear amplification and the rapid changes of cell length (Franchini and Elgoyhen 2006). They are also responsible for the transduction of mechanical activity into electrochemical activity when the stereocilia structures are bent (Gelfand 2010, p.76).

Additionally, the hair cells compensate for the energy consumed for the course of the traveling wave on the basilar membrane, which has as a result the increased sensitivity of the ear and an increased frequency selectivity at low sound intensities (Moller 2013, p.55).

Moreover, according to Franchini and Elgoyhen (2006), the motor protein has especially evolved in the mammalian species in order to support the adaptation of the cochlea. The researchers concluded that there was evidence for the positive selection of prestin only in the mammalian lineage.

Further evidence supporting the motor protein prestin in the mammalian species was the signatures of positive selection on the $\alpha 10$, but on the $\alpha 9$, nicotinic cholinergic receptor (nAChR) subunits (Franchini and Elgoyhen 2006). The $\alpha 9\alpha 10$ -containing nicotinic cholinergic receptor acts as a mediator to inhibit olivocochlear effects on hair cells on the vertebrate species. According to the researchers, the receptor is significant for physiological processes. Specifically, $\alpha 9$ is essential for the development of efferent synapses in the inner ear, and acts as a distinctive source of extracellular

calcium for Ca^{2+} -activated potassium channels in auditory hair cells (Vazquez 2016).

Comparative Research

Based on comparative methodology, Montealegre-z et al. (2012) discovered that the hearing system of mammals and rainforest katyids are similar. More precisely, the insects showed to possess homologous biophysical mechanisms for auditory processing with the auditory structures of the mammalian species, using the three parts of the ear (outer, middle, and inner) to collect and analyze sound. Further evidence was supported by Hoy (2012) who reported that these stages are likely to have evolved firstly in insects and later in mammals.

Further on the mammalian ear, Radojevic et al. (2015) have found evidence of the Akt isoforms, which have a significant role mainly in evolution of the cochlea. More specifically, the kinase Akt is a key downstream mediator of the phosphoinositide-3-kinase signaling pathway, and it is involved in a variety of cellular processes. Akt contains three isoforms, each encoded by a separate gene. On their study, they have indicated that Akt2 and Akt3, but not Akt1, enhance hair cell resistance to ototoxicity. The researchers have highlighted the significance of these isoforms in normal hearing.

Moreover, Warchol (2011) identified that a regenerative ability of the sensory hair cells was lost during the mammalian evolution. To be more precise, Warchol noted that the regeneration failure in the mammalian ear was the result of a trade-off between phenotypic plasticity of supporting cells and sensitive high frequency hearing.

Conclusion

A brief review of the evolution of the mammalian ear was mentioned, as well as a brief discussion about the motor protein prestin as a contributor to the formation of cochlea in mammals. Comparative research on the mammalian ear with other species was also briefly mentioned.

[Intersexual negative inducements](#); [Partner exploitation](#)

Definition

Some forms of mate retention involve the use of deception, manipulation, and exploitation of a romantic partner.

Introduction

Some mate retention tactics are used to manipulate a partner. For instance, in the Mate Retention Tactics Scale, the subscale intersexual negative inducements consists of items that measure behaviors used by one partner to get what he or she wants from the other partner and to provoke negative emotions from a partner (Shackelford et al. 2005). For instance, an individual may flirt with someone in front of his or her partner to cause sexual jealousy. Provoking jealousy may be used as a tactic to manipulate a partner into paying more attention to the individual or to discourage a partner from paying attention to someone he or she is interested in romantically.

Mate Retention in Marriage

Research on married couples shows that mate value plays a role in manipulation of a partner. Mate value is higher for younger women because they have more years of fertility remaining before menopause. Additionally, attractiveness in women is related to mate value, partially because it is related to age (and hence fertility) and health. Men who have significantly younger wives use more mate retention tactics, especially the more costly ones, including emotional manipulation, commitment manipulation, intrasexual threats, and violence against rivals. Men married to women that were significantly more attractive than they were used more mate retention tactics – especially the more costly tactics, including emotional manipulation, wife derogation, intrasexual threats, and violence against rivals (Buss and Shackelford 1997). The bottom line here is that when men are paired with wives who have higher mate value, men use mate retention tactics that manipulate their wives into remaining in the relationship and staying faithful. Women with lower mate value than their partner (those who are older and less attractive), actually use fewer mate retention tactics (Buss and Shackelford 1997), indicating that they refrain from manipulation to keep a partner satisfied and interested in the relationship.

Factors Associated with Romantic Partner Manipulation

Not surprisingly, some personality traits are more predictive of manipulative mate retention tactics. Those who score low on agreeableness, conscientiousness, and openness use more intersexual negative inducements as part of their mate retention strategy. In addition, those who are more emotional use more intersexual negative inducements (Holden et al. 2014). In essence, individuals with these personality traits are more manipulative within their romantic relationships.

Men with lower self-esteem also report using more mate retention tactics. Similarly, wives who esteem their partners less report an increased use of costly mate retention tactics by those partners (Holden et al. 2014). Also, men who report

insulting their partners more also report more intersexual negative inducements. Correspondingly, women who report being insulted by their partners more often also report that their partners use more intersexual negative inducements (McKibbin et al. 2007).

Dark Triad and Intersexual Negative Inducements

The Dark Triad is three interrelated personality traits: narcissism (individuals who are excessively interested in themselves), Machiavellianism (individuals who are cold, calculating, and manipulative to get their way), and psychopathy (individuals who lack empathy and behave in an antisocial manner). Taken together, individuals who score high on the Dark Triad personality traits are comfortable manipulating other people, deceiving them, and exploiting others to get their way. Not surprisingly, these same people are more likely to use mate retention tactics that manipulate their partners, including inducing jealousy in their partner and manipulating their partners' emotions (Jonason et al. 2010).

Other researchers have assessed honesty-humility which has been linked with the Dark Triad. Those who score high on measures of the Dark Triad score low on the personality dimension honesty-humility. Research shows that those who are low on honesty-humility have higher levels of mate guarding and use more intersexual negative inducements, including inducing jealousy and being emotionally manipulative; they use more intrasexual negative inducements, including threatening and fighting rivals; and they use more positive inducements (Holden et al. 2014). Although the use of positive inducements as a mate retention tactic seems contrary to the idea that those low in honesty-humility use costly forms of mate retention to manipulate a mate, it is possible that those scoring low on honesty-humility are willing to use a variety of mate retention tactics to keep a partner interested in the relationship, and although they use a lot of the more negative mate retention tactics, they are also willing to manipulate their mate by using positive inducements. Individuals with low levels

of honesty-humility are frequently willing to use any tactic available to manipulate their partner romantic relationships.

Faking Orgasm to Manipulate a Partner

Although there are many reasons for faking an orgasm, including trying to spare a partner's feelings, sometimes women may fake an orgasm to manipulate their partners. This includes faking an orgasm because "I don't want my partner to have sex with another woman" and "I don't want my partner to think that I am having sex with another man" (McCoy et al. 2015, p. 138). Research indicates that faking an orgasm to deceive and manipulate a partner was related to women's self-reported mate retention tactics. Faking an orgasm to manipulate and deceive a partner was most strongly linked with women's self-reported mate guarding, intersexual negative inducements, and intrasexual negative inducements. Faking an orgasm, at least sometimes, is a strategy to manipulate a partner and may be a way to hide an infidelity or otherwise deceive a partner or keep a partner faithful (McCoy et al. 2015).

Intimate Partner Violence as a Costly Mate Retention Tactic

Perhaps the most costly of all of the mate retention tactics, physical violence against one's partner, may sometimes be used to keep a woman from leaving the relationship. Intimate partner violence is hypothesized to be motivated by sexual jealousy, and men who perceive their female partners as more likely to cheat engage in more physically and sexually violent behaviors (Kaighobadi et al. 2009). Kaighobadi et al. (2008) posit that when men suspect or perceive an infidelity, they might begin with less costly retention tactics such as checking up on a partner or keeping her away from other men and then progress to more violent tactics such as pushing or grabbing a partner. Men who are more antisocial, self-centered, and

impulsive are more likely to engage in intimate partner violence. Also, men who are less emotionally stable, agreeable, and conscientious are more likely to engage in intimate partner violence (Kaighobadi et al. 2008). Although it is an extreme behavior, intimate partner violence may have been selected for if it increased a man's paternity certainty. Research indicates that physical violence by men is predicted by proprietary mate retention tactics and that these mate retention tactics are used more when men perceive that their partner is interested in other men. Like men, women who perceive that their partner is interested in another man use more proprietary mate retention tactics, but these mate retention tactics do not predict physical violence in women (Cousins and Gangestad 2007). These studies indicate that intimate partner violence, at least in men, may be a form of coercive control and may enable some individuals to manipulate a partner's behavior.

Conclusion

Within romantic relationships, people may use some forms of mate retention to manipulate a partner. Some personality traits are related to higher levels of manipulation, including people scoring high on the Dark Triad. Additionally, partner manipulation is more likely in married men who have lower mate value, probably as a means to keep a partner faithful and in a relationship. Married women who have low mate value use fewer forms of manipulation, probably because they do not want to risk losing their partners. In its most extreme form, manipulation may take the form of physical violence which may be used to manipulate a partner into remaining faithful.

Manipulation and Dishonest Signals

Carl Brusse

Department of Philosophy and Charles Perkins Centre, The University of Sydney, Sydney, NSW, Australia

Synonyms

Deception; Influence

Definition

Dishonest signals are displays, calls, or performances that would ordinarily convey certain information about some state of the world, but where the signal being sent does not correspond to the true state. Manipulation is the sending of signals in a way that takes advantage of default receiver responses to such signals, to influence their behavior in ways favorable to the sender. Manipulative signals are often dishonest, and dishonest signals are often manipulative, though this not need be the case. Some theorists have defined signaling in such a way that evolutionarily reinforced signals are essentially manipulative.

Introduction

Signals in the natural world are evolved phenomena, where two actors, the sender and the receiver, use an observable trait or behavior of the sender to direct the behavior of the receiver. The fitness benefits of this relationship for both actors, on average over evolutionary time, help explain why the relevant behaviors evolved. In standard cases, the sender signals conditional on some state of the world which they (alone) have access to, and the receiver responds conditionally to the signal. The conditional strategies of signaling and responding coevolve depending on the fitness

impacts of the receiver's actions (given what the state of the world was), the costs of available signals and responses, and combined effects of the different strategies (Maynard Smith and Harper 2003; Skyrms 2010) (see ► [“Animal Signaling”](#)).

However, evolved response strategies to signals (and other stimuli) are also vulnerable to exploitation via manipulation. If the interests of senders and receivers are not exactly the same, then there will be situations where it is in the interests of the sender to have the receiver behave in a way that is not in the receiver's interests (given the true state of the world). This incentivizes signaling strategies which are dishonest and/or manipulative, and this incentivizes signaling forms and strategies which make dishonest signals more difficult or strategically unwise (see ► [“Costly Signaling”](#)).

Dishonest Signals in Nature

Evolved dishonest signals are well known among insects and other invertebrates, where fitness effects of signaling and manipulation are amenable to study. For example, male fiddler crabs have one large claw used for fighting other males and signaling their capacity to do so (by waving it as a visual signal of relative size and strength). Claws lost in fights can be regrown, but some species cut their losses and prioritize the rapid enlargement of much weaker “dummy” claws, which are ineffective in fighting but can still serve the signaling function dishonestly. Sexual signals such as pheromones are another clear case of manipulable fitness-critical signaling. These signals regulate mating behaviors between partners so that mating occurs when both optimally resourced for the production of viable offspring, with pheromones and other signals triggered by sexual maturity and fertility, and mating behaviors triggered by those signals. One famous manipulator of such systems is the *Ophrys speculum* orchid, which attracts male *Campsocilia ciliata* wasps by producing flowers which mimic the approximate shape of a female wasp and accurately reproduce their pheromones. This is so successful that male wasps preferentially copulate with the flower rather

than with actual females (Ayasse et al. 2003). The payoff for the orchid is pollination, as repeated pseudocopulation carries pollen widely between plants, but the wasp incurs a net fitness cost due to the wasted effort and loss of reproductive opportunity. Developmentally entrenched dishonest signaling between species often involves mimicry, with more common examples being the coloring of some harmless species of arthropods, amphibians, and reptiles to resemble toxic or venomous species, as a deterrent to predators.

Vertebrates, especially those with complex social organization, often exhibit complex, flexible, and voluntary signaling strategies, with a variety of dishonest signals used for conditional advantage against conspecifics. Primate studies show that the use of dishonest signals correlates with cortex size and social complexity (McNally and Jackson 2013). Chimpanzees learn to conceal or suppress signals depending on context, for example, to avoid attention of alpha males, and can be straightforwardly deceptive (De Waal 2007). However, such signaling is often less straightforward and more controversial with respect to measuring fitness impacts and drawing evolutionary conclusions.

This difficulty carries across to the application of signaling theory to communication and deception in humans. Human sociality is mediated by languages and other signals, which in principle can be treated as vast systems of signal and response strategies. However, voluntary human signaling is often based on learned responses rather than developmentally acquired traits; costs and benefits associated with deception or honesty are generally hard to identify with direct fitness payoffs. As with much of ethology, the degree to which animal signaling and manipulation theory is continuous with human social psychology is open to debate.

Contested Definitions

Depending on how signals, dishonesty, and manipulation are defined, dishonest signals and manipulation need not be the same thing. Behavior-altering parasites, for example, clearly manipulate

their hosts without exploiting signal responses. Deceptive manipulation is also possible that exploits environmental responses rather than established signal-response behaviors. For example, the luminescent esca organs of anglerfish are often used to imitate the food sources of prey fish, or otherwise confuse or lure them in for predation. Anglerfish are clearly manipulating their prey via a form of deception, but the responses they take advantage of are not typically responses to *signals* and did not evolve as such, meaning that the traditional “communicative” or co-evolutionary paradigm of signaling does not fit the case well.

In contrast to the more co-evolutionary “information-based” formulation of signaling, some theorists also argue that even honest signals are best seen as cases of manipulation (Dawkins and Krebs 1978; Krebs and Dawkins 1984). Because the fitness benefits of sending a signal are only realized if it influences the behavior of a receiver, it is argued that the primary selected function of signals is to manipulate rather than to communicate or inform. On this way of thinking, all signals are manipulative, but sometimes being manipulated is worthwhile (i.e., when signals are mostly “honest”), and it might sometimes make little difference to the receiver either way. This view therefore retains natural selection as a key component, but only for senders, and its modern proponents argue that it is misleading to link the idea of signaling to the transfer of information/meaning encoded in the signal, or even treat honesty or dishonesty as a primary consideration (Rendall and Owren 2013).

Stability and Dynamics

Regardless of what counts as a signal or as manipulation, the ability of receivers to glean the facts that a sender has access to from their signaling behavior remains evolutionarily significant (sometimes called “mind reading”). Dishonest signals, if treated as veridical, can be directly costly to the receiver. However, in the context of an established, mutually beneficial signaling system, these can also indirectly costly to both senders and receivers more generally due the value of honest, veridical signals being

undermined. This provides incentives for receivers to evolve detection mechanisms and for honest senders to evolve complementary “guarantee” mechanisms.

Among the posited systems of guarantee-detection for mammals (especially humans and closely related primates) are involuntary emotional displays and the ability to rapidly interpret them. Darwin argued that reflexive facial expressions (and other reflexes such as blushing) in humans and other great apes are evolved veridical signals of emotional states (Darwin 1872). Robert Frank goes further, using game theoretic analysis to argue that emotional states themselves evolved as solutions to the threat of dishonest signals. Anger (for example) is seen as an easily identified loss of control which predictably restricts the sender to a dominant course of action, akin to making a show of throwing away the steering wheel of your car in a game of chicken (Frank 1988). Again, the deep human dependence on cultural learning (and potential cross-cultural variation) complicates detailed evolutionary analyses of any particular forms of emotional display or manipulative behavior, though plausible general principles can be posited. In theory, producing and recognizing involuntary, hard-to-fake physiological displays that are directly generated by mental states could be strategically advantageous in competitive social contexts. However, evolving more sophisticated capacities to mimic them would also be advantageous for would-be manipulators, so we should expect to see an evolutionary arms race between intense displays, “acting ability,” and ability to discern genuine anger, fear, and love from manipulative fakery.

The evolutionary dynamics of manipulation therefore follow the general pattern of parasitic relationships. Manipulated receivers often pay a significant fitness cost, so a simple approach to evolutionary theory sees such signals as unstable: the receivers are under evolutionary pressure to alter their strategies to avoid being duped. For example, it might be possible for *Campsoscolia ciliata* wasps to evolve coordination strategies based around alternative pheromone signals that the orchid finds harder to mimic. But this would depend on generation time and other factors in the comparative evolvability of both species. The

persistence of *Ophrys speculum*'s manipulations might therefore be the result of it rapidly adapting to produce any pheromone the wasp uses. Alternatively, there might be an ongoing chemical arms race: with the wasp occasionally switching pheromone signals and the orchid racing to catch up. Another possibility is that the fitness costs to the wasp of being manipulated never rise to the level that a difficult. It is also worth noting that the orchid's breeding strategy makes it an obligate manipulator of the wasp, and therefore it too will suffer if its fitness impact on them is too great. It is therefore possible that the manipulative signaling relationships might be self-regulating, such that selection pressure on receivers stays at levels too low to make adaptive escape worthwhile.

Conclusions

Signaling theory provides a broad framework to approach the evolutionary psychology of communication, deception, and manipulation. Furthermore, evidence from primate studies suggest that deception and the capacity to deceive is linked to need to navigate and exploit social structures and relationships. Deception almost certainly evolved alongside communication, cooperation, and social complexity in our recent evolutionary past, and in principle, it can be understood in simple game theoretic terms that are applicable to evolutionary explanation. In practice though, due to the relative complexity and cultural dependence of humans with respect to their psychology, societies, and signaling systems, the productive application of these principles in psychological research remains a challenge.

Definition

Theoretically, manipulation by others into committing acts of suicide terrorism is a form of duplicity in which an individual or group activates evolved mechanisms (i.e., kinship psychology or

mating psychology) that over evolutionary time produced reproductive benefits; however, the benefits in relation to suicide terrorism are not forthcoming and results in maladaptive behavior.

Introduction

Suicide terrorism is an act of outward aggression in which the perpetrating agent willfully sacrifices his or her own life with intent to inflict as much damage as possible on civilian casualties. Suicide terrorism is systematic and often perpetuated by political organizations (e.g., Hamas, Al-Qaeda, Tamil Tigers, among others) that disseminate messages to followers through various media outlets and often train adherents in institutionalized settings apart from their natal residences. Some evolutionary theorists hypothesize that these institutions convince followers to partake in suicide terror missions by manipulating evolved psychological mechanisms i.e., kinship psychology and mating psychology. According to these models, terror organizations use tactics that piggyback on these evolved mechanisms; however, the evolved benefits are not forthcoming as the cues are deceptive. Thus, these hypotheses are distinct from evolutionary models of suicide terrorism, which contend that the act incurs manifest fitness benefits.

Theories and Evidence for Suicide Terrorism as Manipulation by Others

The two most popular evolutionary explanations for suicide terrorism contend that terror organizations recruit suicide attackers by manipulating evolved psychological mechanisms. Informed by kin selection, the first explanation claims that terror institutions effectively deceive would-be suicide attackers by acting on kinship mechanisms, thus facilitating self-sacrifice (Qirko 2004, 2009, 2013). The second explanation argues instead that sexual access manipulations form the basis of the underlying motivation for suicide terrorism (Kanazawa 2007; Thayer and Hudson 2010). Though there is data that backs both hypotheses, each suffers from theoretical and empirical impediments.

Brief overview of kinship psychology manipulation: The hypothesis that terror organization manipulate followers into accomplishing suicide missions by deceptively activating kinship psychology rests on the theory of kin selection (Hamilton 1963; Smith 1964). According to Hamilton's rule (1963) an organism should act altruistically if the reproductive benefits to its kin outweigh the costs of the act to the organism. Mathematically, Hamilton's rule is represented by $rb > c$ where r is the degree of genetic relatedness, b is the reproductive benefits to related kin, and c is the cost to the agent. Kin selection was a groundbreaking evolutionary theory that demonstrated how traits that harm individual organisms could be selected for in a population.

In order for an organism to act altruistically, there must be a means for it to distinguish kin from non-kin, using kin recognition cues to calculate the degree of genetic relatedness (r) between the self and other. Hypothesized cues of genetic kinship among humans include physical proximity during development, shared phenotypic traits, and the use of kinship terminology (Qirko 2004; Alexander 1990; Michener and Fletcher 1987; Hamilton 1964; Sherman 1985). Qirko (2004, 2009, 2013) predicted that institutions that seek out recruits for suicide missions would employ the following tactics: (1) prefer recruits in earlier stages of development; (2) separate recruits from their genetic kin; (3) promote the use of kin referents between group members; (4) encourage the use of markers that mimic shared phenotypes (e.g., uniforms or other identifiers); and (5) facilitate close proximity among the in-group members in the institutional setting. Evidence indicates that, in fact, terror organizations often employ these strategies to foster a sense of kinship among group members.

Brief overview of sexual access manipulation: Alternatively, some theorists have proposed that the promise of access to mates in the afterlife (i.e., 72 virgins) is a central motivator for suicide terrorism (Kanazawa 2007; Thayer and Hudson 2010). The promise of sexual reward, though deceptive, relies on mechanisms for reciprocal altruism wherein one agent assists to increase the fitness of another agent at an initial cost to itself on the assumption that the first agent will be assisted

in kind in the future (Trivers 1971). Kanazawa (2007) claims that the sanctioning of polygyny in Islam creates a reproductive skew, effectively excluding younger males from the mating market. Islamic terror organizations highlight sexual rewards in the afterlife in their discourses, a teaching that is downplayed or contested by other factions of Islam. Furthermore, the acquisition of rewards in the afterlife, including sexual access, is a commonly cited motivator among Palestinian combatants (Hafez 2006).

In a similar vein, the esteem afforded suicide terrorists in death by local communities is an indirect means through which terror networks might access male mating psychology. High social status is correlated with reproductive success in humans and non-human primates (Smith 2004), which is directly linked to risk taking behavior in the realm of intrasexual selection (Daly 2001).

Overall, the empirical evidence to support the sexual access manipulation hypothesis of suicide terrorism is minimal. Sexual access manipulations might factor into cost-benefit calculations; however, this mechanism alone appears insufficient to explain suicide terrorism, especially since many suicide attackers are not low status at least in terms of income and education (Atran 2003; Berrebi 2003). Moreover, as highlighted by Lawson et al. (2008) the rates of polygyny are fairly low in these populations, and the percent of never married males in Islamic populations is about the same as in the West (United Nations. Dept. of Economic and Social Affairs, Population Division 2004).

Conclusion

Terror organizations regularly rely on strategies to solicit followers for suicide attacks that appear to directly act on psychological mechanisms with well-demonstrated evolutionary benefits. These institutions foster a sense of kinship among their members, and they often perpetuate religious teachings that promise sexual rewards in the afterlife for martyrdom.

Manipulative Use of Kin Terminology

Anna Rotkirch

Population Research Institute, Väestöliitto – Finnish Family Federation, Helsinki, Finland

Synonyms

Fictive kin; Induced altruism; Induced nepotism

Definitions

Humans use language to recognise kin, and this ability can be extended to fictive kin such as close friends and ideological allies. Our closest genetic family ties, denoting one-half degree of genetic relatedness (“sister”, “brother”, “father”, “mother”, “child”), are typically used to signal strong social bonding and manipulate group identity. More distant terminology, denoting one-fourth to one-eighth degree of relatedness such as “cousin”, “aunt” and “grandparent”, appears to be less frequently used. Cross-generational terms denote respect and dominance, while within-generational terms signal solidarity and closeness. The use of fictive linguistic kin terms is a major strategy in the institutional manipulation of individuals.

Introduction

Our first strong attachments are typically formed to parents and siblings. The connotations of these terms have made their metaphorical use common throughout cultures. The aim is to evoke the positive emotions characteristic of close family ties and induce kin-specific behaviour, such as

altruism and loyalty, among individuals who are distantly or not at all related to each other. The manipulative use of kin terminology can concern different social situations, ranging from dyadic bonds to kin lineages, group identity, organisations and mass ideologies.

Language is central for human kin recognition beyond the nuclear family. Linguistic kin recognition can itself be used manipulatively, so that kin membership is expanded or contracted depending on social alliances and individual interest. Such use has been depicted in traditional societies: for instance, an ally can be assigned or deprived of the status of “cousin” (Qirko 2011). In societies where spouses are selected among relatives, individuals may stretch kin assignment in order to allow themselves a greater choice of mates (Chagnon 1988).

Affinal kin, present when kin lineages are joined through marriage, assign each other specific terms, such as “mother/daughter-in-law” (Hughes 1988). This linguistic and emotional capacity to “make kin” through marriage of previously distantly or unrelated individuals appears to be a human universal. If so, it can be assumed to have evolved together with the human cooperative breeding system and language use. In socially complex societies, the ability to “make kin” can further be employed to create kin-like bonds between friends and allies. This allows also for political manipulation, such as referring to neighbouring countries as “brothers”.

It is useful to distinguish between manipulative use of kin terms in dyadic bonds and in large social groups.

Manipulation of Dyadic Bonds

Between two individuals, referring to non-kin as a father, mother, sister, brother or cousin serves to enhance a social relation. The kin metaphor strengthens the mutual relationship as well as signals its significance to others, manipulating social behaviour towards both parties of the dyad. “Like a sister” or “my brother” denotes loyalty, similarity,

trust, and long-term willingness to provide help and support, while “a cousin” – more rarely used in contemporary societies – can denote alliances and cooperation. Cross-generational terms such as “father” or “mother” signify reverence or apprenticeship, and “my daughter”, “son” or “child” a protective and nurturing relationship that may resemble adoption or fostering. (Qirko 2011.)

With the exception of “child”, which can be used for a young lover, the usage of fictive kin terms is usually reserved for non-sexual relations. The grandparental tie is not commonly invoked to describe or manipulate feelings towards non-kin in dyads.

Kin terminology is also employed to signal respect and benevolence. In hierarchical cultures, generic greetings may involve kin terms to denote age and gender hierarchies.

Manipulation of Ideological Communities

Once large and complex social institutions appeared, humans faced the novel problem of enabling co-operation and altruism in groups of several hundred or thousand members and between individuals who may not even have met each other. In this context, kin terminology can enhance group loyalty by tapping into evolved dispositions for kin altruism and fairness (Johnson 1986). People do not actually start believing that they are related to such metaphorical kin. Instead, kin terms are intended to evoke an emotional response that will trigger more altruism and solidarity towards the individual’s own group (Salmon 1998) or more hostility towards the outgroup (Abou-Abdallah et al. 2016). Indeed, as van den Berghe noted (1981, p. 60), large-scale group inequality is “almost invariably bolstered by an ideology that disguises the parasitism of the ruling class as either kin selection or reciprocity”.

Institutions that require costly sacrifice from its members – for instance, putting one’s life at risk or foregoing reproduction – can be expected to encourage close association, similar physical outlooks, and the use of symbolic kin terminology

among its members (Qirko 2013). This is why, for instance, armed groups or ethnic subcultures tend to dress the same way, speak the same way, and refer to each other as “brothers” or “sisters” of the same “family”. Such manipulation can also include measures intended to weaken or destroy bonds to biological family members. For instance, monasteries and the early universities required members to remain unmarried and never have children, and religious sects may encourage members to refrain from contact with their parents and siblings.

Political and religious movements demanding less costly adherence also employ kin metaphors manipulatively. Notions of brotherhood and sisterhood are commonly applied within ideological movements, from the “Freedom, Equality, Brotherhood” slogan of the French revolution to the “Muslim Brotherhood” political movement in the contemporary Arab world. Gods are often provided with paternal or maternal features, as are leaders in authoritarian states. Ideological communities may structurally mimic the nuclear family: the rulers are “parents”, followers are their “children” and “sisters” or “brothers” to each other. The term “spouse” is also metaphorically used within some religious communities, e.g. the “brides of Christ” –perhaps tapping into the psychological similarity of religious and romantic ecstasy (Dunbar 2010).

Monotheistic religions and nationalistic movements have prominently used kin metaphors. It has therefore been suggested that they function as “kinship surrogates” in large populations. These ideologies appear to trigger feelings of belongingness similar to those that would have been induced by kinship in traditional, small-scale societies. However, it may be that the use of kin metaphors on a political level has become less efficient in a multi-racial, multi-national world (MacIntyre 2004), at least among liberal political movements.

Theoretical research on the manipulative use of kin terminology was first developed in the early stages of sociobiology (e.g., van den Berghe 1981). Empirical studies have since been able to demonstrate associations between patriotism and usage of kin metaphors in the United States

(Holper 1996). The effects of kin metaphors on the user have been found to vary with political adherence (Garst and Bodenhausen 1996) and with birth order, so that middle-borns were less likely to be affected than were first and last borns (Salmon 1998). With data from Lebanon and Australia, another study found that metaphors of “brotherhood” boosted the hostility towards out-group members (Abou-Abdallah et al. 2016). However, there is a scarcity of empirical studies concerning the mechanisms and effects of the uses of kin terminology in different societies.

Conclusions

Kin terms can be stretch and assigned as a way of manipulating social relations. In everyday social life, linguistic kin recognition can affect which individuals are treated as if they were genetically related. In complex and hierarchical societies, manipulative and metaphorical use of kin terminology is also common. Institutions and social movements may use kin terminology in order to evoke altruistic behavior and a sense of obligation. Such metaphorical use typically refers to the parent-child bond or to brotherhood and sisterhood. In extreme cases, authoritarian groups manipulatively use kinship terms in combination with a dismissal of biological family ties.

Definition

Marc Bekoff is an author and researcher in the area of animal behavior, cognition, and behavioral ecology and works extensively for animal conservation.

Introduction

Dr. Bekoff is a Professor Emeritus of Ecology and Evolutionary Biology at the University of Colorado in Boulder, and is a Fellow of the Animal Behavior Society and a past Guggenheim Fellow. Together with Jane Goodall, Dr. Bekoff cofounded Ethologists for the Ethical Treatment of Animals in 2000 and received the Exemplar Award from the Animal Behavior Society for major long-term contributions to the field of animal behavior that same year. He has published numerous books and articles focused on animal emotion, cognition, and welfare, which have been featured in several popular science and news publications, including *48 Hours*, *Time Magazine*, *Life Magazine*, *U.S. News and World Report*, and *The New York Times*. Dr. Bekoff currently writes a science column about animal emotion for *Psychology Today* (Bekoff 2016a).

About the Author

Bekoff is originally from Brooklyn New York, and received his A.B. in Anthropology from Washington University in St. Louis, Missouri. He went on to receive his M.A. in Biology from Hofstra University in Hempstead, New York, and then became a graduate student in Neurobiology and Behavior at Cornell University. He ultimately received his Ph.D. from Washington University in Animal Behavior and has focused his research on behavioral ecology and conservation. He has published extensively on human-animal interactions, emotions, nonhuman morality, and animal protection (Bekoff 2016a, b).

Animal Emotions

Bekoff spent decades studying a diverse group of animals — from coyotes in Wyoming to penguins in Antarctica, viewing their cognitions and behaviors from an ethological perspective (Bekoff 2016a). In his book, *Minding Animals: Awareness, Emotions, and Heart*, Bekoff (2002) offers readers detailed accounts of animal behavior, including grooming and gossip, self-medication, feeding patterns, dreaming, dominance, and mating behavior. Not only does Bekoff provide evidence of advanced cognitions in other animals, such as chimpanzees who medicate themselves with herbal remedies, and elephants who mourn dead group member, but Bekoff also sheds light on many of the more serious issues surrounding these animals. He offers an overview of animal cognition, intelligence, and consciousness, presenting examples of animal passions, and highlighting the presence of deep emotional lives in our animal kin. Bekoff strongly promotes animal protection and well-being in light of understanding animal emotions (Bekoff 2016b). He urges a new paradigm of respect, grace, compassion, and love for all animals.

Following his years of experience studying communication patterns in a wide variety of animals, Bekoff (2007) further advocates the presence of rich emotional lives in all animals in his book, *The Emotional Lives of Animals: A Leading Scientist Explores Animal Joy, Sorrow, and Empathy – and Why They Matter*. Bekoff explains that humans are not exclusive in their emotional experiences of love, empathy, and compassion and that animals of many species feel these same sentiments. This requires humans to think differently about our current domination and abuse of animals, particularly in the field of research. In this book, Bekoff (2007) highlights recent scientific research confirming the existence of emotions in animals, and blends them with related anecdotes of animal grief, joy, embarrassment, anger, and love – emotions that humans have recognized in animals for years. Importantly, Bekoff explores the evolutionary mechanisms supporting these emotions, including underlying brain structures

and cross-species analyses, and advocates the use of noninvasive neurological techniques to reduce negative emotional experience for animals in research. This book exemplifies Bekoff's call for reevaluating how our actions negatively impact the emotional lives of animals, and highlights the importance of ethical and compassionate treatment of animals across scientific domains.

Cognitive Ethology

Cognitive ethology is a branch of ethology concerned with how conscious awareness and purposeful intention influence the behavior of animals (Collins 2012). In this approach, Tinbergen's four questions regarding the evolution, adaptation, causation, and development of behavior (see Ristau and Erlbaum 1991) are applied to investigations of animal cognitive awareness. This combination of cognitive science and ethology promotes the idea that animals should be observed under natural conditions so that researchers can understand the evolutionary explanation, adaptive function, proximate causation, and lifespan development of any species-typical cognition (Ristau and Erlbaum 1991).

Bekoff and Allen (1997) identify three major groups of people with different views on cognitive ethology: (1) *Slayers* deny any possibility of success in cognitive ethology, (2) *Proponents* keep an open mind about animal cognition and the utility of cognitive ethological investigation, and (3) *Skeptics* stand somewhere in between. According to Bekoff (1995) only Proponents converge with animal rights thinking in seeing animal experience as worthy in itself. As a primary example of proponent thinking, E.O. Wilson (1984) coined the term "biophilia" to describe the innate desire shared by living beings to associate and attend to other living organisms. According to Bekoff (1995), researchers can and should investigate the ethology of animal emotions, particularly within their natural habitats.

In this collection of revised essays, titled *Why Dogs Hump and Bees Get Depressed: The Fascinating Science of Animal Intelligence, Emotions,*

Friendship, and Conservation, Bekoff (2013) discusses the expanding field of anthrozoology, or the study of human-animal interactions. A major aim of anthrozoologic research to quantify positive effects of human-animal relationships from either the human or animal perspective (Mills 2010). Bekoff (2013) outlines empirical and anecdotal evidence of emotional cognitions in animals, including empathy, grief, humor, and love. For example, humpback whales protect gray whales from orca attacks, combat dogs suffer from PTSD, and bees display thrill-seeking tendencies. In light of these animal emotions, Bekoff implores others to employ an "ethical compass" when interacting with all species within the animal kingdom.

Furthermore, in *Species of Mind: The Philosophy and Biology of Cognitive Ethology*, authors Marc Bekoff and Colin Allen (1999) make it clear that many animals have rich cognitive lives. They also believe that it is just as important to investigate evolutionary foundations of animals' thoughts and emotions just like comparative studies of physical attributes, such as kidneys, stomachs, and hearts. Although Bekoff advocates the comparative, evolutionary, and ecological aspects of the mental phenomena of animals, this book shows how philosophy and cognitive ethology together can give a more holistic, analytical approach to animal cognition. Philosophy can provide cognitive ethology with an analytical basis for the attribution and assessment of cognition to nonhuman animals, whereas cognitive ethology can help philosophy to explain mentality in naturalistic terms by providing data on the evolution of cognition. This reciprocal relationship between philosophical theories of mind and empirical studies of animal cognition is exemplified by the authors' presentation of case studies, particularly in the areas of antipredator vigilance and social play, where there are many points of contact with philosophical discussions of intentionality and representation. The authors make specific suggestions about how to use philosophical theories of intentionality as starting points for empirical investigation of animal minds. They also discuss cognitive ethology's relevance to questions of ethics, as our beliefs about the mental

lives of animals strongly affect our attitudes toward their moral status.

Conclusion

Marc Bekoff is a central figure in research on animal emotions, cognition, and compassionate conservation. Using his vast experience observing diverse animal species in the natural world, Bekoff promotes the idea that humans are one among many animals and urges his audience to treat all animals with compassion and respect. Because animals feel many of the same emotions as humans (e.g., Bekoff 2002), it is imperative that humans minimize any emotional suffering when interacting with other species. Further research should focus on the evolutionary foundations, adaptive functions, proximate mechanisms, and development of animal cognition, with the hope of understanding the rich emotional lives of animals. With this knowledge, humans have the core responsibility of ensuring both the physical and emotional safety of the animals with whom we share this planet.

Definition

Margie Profet contributed evolutionary theories of pathogen and toxin avoidance as they pertained to pregnancy sickness, allergies, and menstruation.

Introduction

This entry focuses on the theoretical contributions made by Margie Profet in the late 1980s and early 1990s. Profet's key contributions included describing the adaptive significance of pregnancy

sickness, menstruation, and allergies. Prior to Profet's work, researchers had not explained these topics through the lens of evolutionary theory; instead, these physiological processes were largely portrayed as biological anomalies or evolutionary by-products. Profet was therefore recognized as a key figure in bridging evolutionary theory with health sciences, but also stirred up controversy among biologists and physicians in the popular media. This entry therefore describes each of the key contributions made by Profet and the social context surrounding her theories.

Background

Margaret "Margie" Profet was born August 7, 1958. She grew up in Manhattan Beach, California, and was the daughter of two engineers (Martin 2012). Margie was a key figure in the development of evolutionary theories of biological processes; however, her educational training did not include formal studies in evolutionary biology. Instead, she received bachelor's degrees in Political Philosophy from Harvard University (1980), and another in Physics from the University of California, Berkeley (1985). She briefly worked as a research associate at UC Berkeley and as a visiting scholar in Astronomy at the University of Washington in Seattle. She began to pursue a PhD in anthropology from Harvard University, but did not finish the degree (Martin 2012). In online interviews conducted with Profet, she is quoted for having a distaste for formal education, and even comparing academia to a jail sentence (McDermott 1994). Thus, instead of completing a PhD, she pursued her research interests independently.

Margie Profet's self-guided academic pursuits led to the development of three formative publications that shaped early understanding of human behavior and health through the lens of evolutionary theory. These novel theories explained the adaptive significance of pregnancy sickness, menstruation, and allergies. She was awarded a MacArthur Foundation Genius Fellowship in 1993 for these theoretical contributions. According to an article published in *Newsweek* (2009), her

award summoned the attention from multiple news reporters who were enthralled by her ideas that altered the way the public viewed women's bodies. Each of her contributions is described below.

Pregnancy Sickness

The first theory developed by Profet proposes that pregnancy sickness evolved as an adaptive strategy to protect women from ingesting teratogenic substances. **Teratogens** are any environmental or chemical agent that can disrupt fetal development. In pregnancy, teratogens can be found in environmental toxins, such as cigarette smoke, or in plant toxins, such as nicotine. Profet's theory was motivated from earlier research by Hook (1978), who proposed that pregnancy sickness evolved during the agricultural revolution because women's avoidances often targeted agriculturally based products, such as beer. Profet disagreed with this hypothesis, suggesting that it failed to account for women's frequent exposure to plant toxins during the Pleistocene Era. According to this model, **plant secondary compounds**, which are produced by plants to deter predators, elicit toxin avoidance mechanisms in humans, with the first line of defense being bitter and pungent tastes. This hypothesis is supported by evidence that pregnancy sickness is experienced primarily during the first trimester of pregnancy, when placentation and embryogenesis occur, making the fetus particularly vulnerable to teratogens. Nausea, vomiting, and aversions to potentially teratogenic substances therefore prevent the ingestion of items that could harm fetal growth and development.

Profet's evolutionary theory of pregnancy sickness was published in *Evolutionary Theory* in 1988, and the book, *The Adapted Mind: Evolutionary Psychology and the Generation of Culture* in 1995. She also published her theory in popular books, entitled *Protecting Your Baby-to-be: Preventing Birth Defects In The First Three Months Of Pregnancy* (Profet 1997b), and *Pregnancy Sickness: Using Your Body's Natural Defenses To Protect Your Baby-to-Be* (Profet 1997a). These books were published as guides for new mothers to better understand the body's evolved defenses during pregnancy. Profet also offered

advice to women regarding the types of food they could safely consume.

News reporters latched onto Profet's pregnancy sickness theory, often bringing attention to her controversial recommendations for pregnant women to avoid plant-based foods. Medical doctors were often cited in these articles, claiming that Profet's theory was unfounded. In a Newsweek article entitled, *Babies, Broccoli, and Birth Defects*, one doctor claimed that the vegetables Profet cautioned against were unlikely to have a harmful level of toxins that would actually cause birth defects (Newsweek Staff 1995). The doctor argued that bitter taste aversions in pregnancy were instead a byproduct of hormonal shifts that occur during pregnancy.

Formal empirical tests of Profet's pregnancy toxin-avoidance hypothesis, however, have generated mixed findings. After her paper was published, Fessler (2002) and Flaxman and Sherman (2000) proposed that women were perhaps more likely to feel averse to meat and dairy products because these items were more likely to harbor pathogens. Flaxman and Sherman (2000) tested their hypothesis with the ethnographic record and found that pregnant women were more likely to avoid meat and dairy products rather than vegetables. More recent investigations of women's pregnancy aversions in non-Western societies have been more varied, with some women reporting aversions to foods with toxins (McKerracher et al. 2016; Placek et al. 2017), staple foods (Young and Pike 2012), and other studies showing that food aversions target animal products (Henrich and Henrich 2010; McKerracher et al. 2016).

Allergies

In 1991, Profet published her second major contribution in the *Quarterly Review of Biology*, arguing that allergies evolved as a last line of defense against toxins, including toxins from ingested foods, injected drugs and venoms, inhaled substances, skin allergens, and helminths. Her motivation for developing this theory originated from former arguments that explained allergies as either an immunological malfunction or as a defense against helminth infections. Profet argued that

these perspectives were inadequate because the symptoms associated with allergic reactions instead show evidence of toxin avoidance. Specifically, mammalian interactions with allergens often result in coughing, vomiting, sneezing, diarrhea, tearing, and scratching. These symptoms may assist the host to rapidly expel the toxins and/or slow the rate of circulation of the toxins. In reference to helminths, Profet suggested that rather than thinking of allergies as responses to helminth infections, that perhaps one should consider the role helminths have in releasing toxins into the bloodstream, which subsequently induce an antibody response via elevated IgE antibodies.

Profet relied on several lines of evidence to support her antitoxin hypothesis of allergies. As an example, the drop in blood pressure during an allergic reaction can reduce the circulation of toxins in the blood stream. Profet also pointed out that allergic reactions become stronger with repeated exposure to toxins. Profet stated that this evidence supports her hypothesis because toxin exposure can have a cumulative effect, whereas the successive contact with a toxin usually implies that it is avoidable, unlike helminths, which are typically unavoidable and can often lead to sudden death (Profet 1991).

The antitoxin hypothesis of allergies also included a discussion of the inverse relationship often found between allergies and cancer (Profet 1991). Profet suggested that although allergies were not specifically designed to fight against cancer, that perhaps they function as anti-cancer agents by expelling mutagenic and carcinogenic toxins.

In contrast to the pregnancy sickness hypothesis, Profet's antitoxin theory of allergies received more positive support, particularly as it applies to cancer. In a review of the literature, researchers Sherman et al. (2008) found support that cancer rates were inversely related to allergies; however, this relationship varied according to the specific type of cancer. The authors concluded that their findings overwhelmingly supported Profet's prophylaxis hypothesis that allergies expel carcinogenic and mutagenic toxins from the body, leading to lower rates of specific cancers. Another study conducted by Cotterchio et al. (2014)

further supported Profet's hypothesis in which hay fever was associated with a significant reduction in pancreatic cancer risk.

Menstruation

Profet's (1993) third major theoretical contribution explained the adaptive significance of female menstruation, which was published in the *Quarterly Review of Biology*. According to popular media, Profet's theory of menstruation came to her during a dream, where she reportedly saw "black triangles embedded in red" and interpreted these symbols as pathogens being washed away by menstrual blood (Martin 2012). Profet relied on evidence from nonhuman mammals to demonstrate that female menstruation was a defense against pathogens transmitted by sperm. The development of this theory was motivated by the fact that no formal theories of menstruation existed. Prior to Profet's theory, much of the research focused on menstruation as a non-functional by-product of reproductive cycling or as a constraint to reproductive effort. Other researchers at the time proposed that menstruation might function to rid the body of dietary phytoestrogens (Garey 1990), or shed fetal cells that might otherwise alter maternal metabolism and behavior if not aborted (Haig 1993). Profet argued that none of these prior hypotheses could account for the ultimate explanation of menstruation in women, or why menstruation evolved in human females during the Pleistocene era. Profet also argued that the prevailing perspectives were limited because menstruation is costly for women in terms of nutritional loss in the form of iron, along with other costs, such as reduced amount of time available for conception to take place.

According to Profet, her theory targeted the key question as to why the body does not simply reabsorb the uterine lining, but instead engages in such an energetically costly act each month of nonpregnant cycling. In her paper, she provides an example from Rhesus Monkeys who absorb a portion of the uterine lining after the menstrual cycle is complete (Profet 1993). Humans, on the other hand, shed the uterine lining. Profet predicted that if menstrual bleeding evolved and

currently functioned as an antipathogenic strategy, that it would be (1) either universal or nearly universal among mammals; (2) if not universal, then menstruation would be less common in species that have a higher probability of pregnancy; (3) the volume of blood expelled during menstruation would be associated with body size of the mammal and mating strategies. In other words, larger bodied animals who engage in promiscuous mating would have heavier menstruation than smaller bodied animals who are monogamous. This rationale was based on the notion that menstruation is energetically costly to maintain; and (4) other forms of uterine bleeding that are not associated with the monthly menstrual cycle would also have an antipathogen effect. Profet relied on evidence from human and nonhuman mammals to support her theory and also discussed other forms of uterine bleeding in relation to infection risk. One study she cited, for instance, indicated that sexual intercourse during the last 2 months of pregnancy resulted in a higher rate of infection, leading to lower reproductive success via premature delivery (Naeye and Ross 1982).

Among Profet's three theories, her predictions for menstruation were perhaps the most debated. After her paper was published, she received mixed reviews. Initial support for her ideas came primarily from evolutionary psychologists who applauded her efforts. Others were more skeptical (Angier 1993). Profet responded to criticisms from reproductive biologists and gynecologists by stating that they had insufficient training in evolutionary theory. Later, Profet's theory of menstruation was further deconstructed by other evolutionary theorists (see Clancy 2009 for a review).

Conclusion

In summary, Margie Profet was among the first to combine evolutionary theory with health sciences. Her primary contributions included three influential theories on the adaptive significance of pregnancy sickness, allergies, and menstruation. Her contributions were significant for her time because few researchers had attempted to understand why these physiological processes evolved.

Soon after the development of these theories, Profet stopped publishing evolutionary theories of human psychophysiology, with possible explanations available on popular media channels (e.g., Martin 2012). Despite the empirical outcomes of her ideas and her own personal trajectory, Margie Profet made a significant impact on evolutionary biology, with contributions that set the stage for further investigations of pathogen and toxin avoidance strategies in humans and nonhuman mammals.

Maria Montessori

Patrick Frierson

Whitman College, Walla Walla, WA, USA

Definition

Maria Montessori (1870–1952) was an Italian physician and psychiatrist who became the founder of a new “scientific pedagogy” based on careful observation of children and informed by her distinctive approach to evolutionary psychological science.

Introduction

Maria Montessori was born in Chiaravalle, Italy, in 1870. As a child, she insisted – against the wishes of her father – that she be enrolled (as the only girl) in a school for future engineers. By 1890, she was one of first women enrolled in the medical school at the University of Rome. She quickly rose to the forefront of her medical school class and gained the esteem of Guiseppe Sergi, one of the leading psychologists in Italy at the time. Alongside Sante De Sanctis and Giuseppe Montesano, who both went on to play pivotal roles in Italian experimental psychology, Montessori was one of Sergi’s top students. In 1896, she graduated from the University with a thesis in

clinical psychology (supervised by De Sanctis, cf. Foschi 2012). The same year, she served as a representative from Italy to an international women’s conference in Berlin, and she began working in clinical psychology in public hospitals in Rome. By 1900, she was teaching courses in pedagogical anthropology and working in a mental hospital that specialized in the treatment and education of “deficient” children. In this context, she engaged with the writings of Jean Marc Gaspard Itard and Édouard Séguin. She remained involved in public advocacy for women (e.g., at a major women’s conference in London in 1899) and began more actively advocating for children’s education. In 1902, she returned to the University of Rome, now as a student of philosophy, in order – as she put it – to “undertake the study of normal pedagogy and of the principles upon which it is based” (Montessori 1912/1909: 33). At the University, she was exposed to the ideas of Rousseau and Pestalozzi, but also – through professors like Antonio Labriola – to Hegel, Marx, and Nietzsche. Her interest in psychology, combined with an interest amongst Italian students in pragmatism, led her to engage seriously with William James. And she continued her engagement with the evolutionary positivism of Sergi and De Sanctis. By 1906, she was teaching courses in Pedagogical Anthropology at the pedagogical school of the University of Rome.

The pivotal moment in her transition to become a global leader in children’s education came in 1907, when she was invited to run a “Children’s House” that would be part of a progressive new approach to low cost housing in the San Lorenzo district of Rome. She had complete control over this classroom and used it as a laboratory for pedagogical techniques. In this context – described in detail in Montessori 1912/1909 – she developed new teaching methods and materials and formulated the basic principles of her educational philosophy. Her *Metodo della Pedagogia Scientifica applicato all’educazione infantile nelle Case dei Bambini* (1909), translated into English with the regrettable title *The Montessori Method* (1912), made her an instant international sensation. Visitors travelled to Italy to study her educational methods, and she travelled throughout the world (including the World’s Fair

in California in 1915) training teachers in her method and presenting her ideas about children's development and scientifically informed pedagogy. She left her private medical practice, her work at the children's hospital, and her professorial teaching at the University of Rome to spend the rest of her life further developing her pedagogy by applying more theoretical rigor, incorporating further experimental results, and expanding the scope of her education to include all stages of life from infancy through adulthood. She promoted her philosophy through books, lectures, publications and international training courses that would equip others to educate children in accordance with her method.

The core principle of her pedagogy is to "Follow the child," that is, to accord the child complete liberty while providing the resources the child needs to use that liberty well. This liberty is not a reckless license; for Montessori, the indication that a child has an environment conducive to liberty is that a child finds opportunities for sustained attention on self-chosen work. Thus, the educator must provide a carefully prepared environment with sufficient resources for the child to freely choose work that sustains attention and fosters development, and the educator must then allow the child to develop herself. In the context of her observations of children, Montessori noted distinct "sensitive periods" of the development of fine-grained psychological traits and skills. She paid careful attention to the emergence of cognitive and social skills and to the essentially embodied nature of these skills, and she developed activities and material conditions to support progress through sensitive periods. She articulated a unique approach to "character" and to the socialization of human beings from infancy through adulthood. She applied her ideas to understanding human progress in general and even advocated for political change through education.

Montessori's overall philosophy and her approach to developmental psychology are spread throughout her many publications and lectures. The most important sources for specifically understanding Montessori's approach to evolutionary theory are her *Pedagogical Anthropology*

(Montessori 1913/1910), where she directly tackles the evolutionary theories of her contemporaries; her elementary materials (particularly *From Childhood to Adolescence* (Montessori 2007/1948) and *To Educate the Human Potential* (Montessori 1993/1948)), where she describes how the basic nature of the universe should be taught to elementary school children; and occasional essays such as "The Unconscious in History" (Montessori 2012/1948) that directly tackle metaphysical themes. Her approach to experimental psychology comes out best in *Montessori Method* (Montessori 1912/1909), *The Formation of Man* (Montessori 2007/1955), and – specifically in terms of her engagement with Freud – *The Secret of Childhood* (Montessori 1966).

In the rest of this entry, I discuss Montessori's general approach to evolutionary psychology and her account of the proper nature of experimental psychology, and then I briefly touch on how her evolutionary psychology relates to her pedagogy.

Evolution and the Spiritual Embryo

One of Montessori's key theoretical insights was her concept of the "spiritual embryo," the notion that human beings are born in a psychologically embryonic stage. Substantively, this implies that children are forming their basic psychological structures during the first six (especially the first three) years of life. Methodologically, it implies that many of the principles of embryology can be used to understand early childhood development. And systematically, the emphasis on embryology informs Montessori's whole conception of biological systems and even her theory of evolution.

In one of Montessori's earliest publications, she explicitly discusses different theories of evolution, and while she acknowledges "the glorious leadership of Darwin" (Montessori 1913: 5), she describes his theory (alongside those of Lamarck and St. Hilaire) as a "mechanical or materialistic theory of evolution" according to which "the environment is regarded as the chief cause of the evolution of organic forms" (Montessori 1913:

46). In preference to such theories, she endorses “other less familiar theories of evolution” proposed by Carl Naegeli, Gregor Mendel, and especially Hugo deVries (Montessori 1913: 46–51). These theories are informed by close investigation of biological *development*, and they “attribute the variability of species to *internal*, rather than external causes – namely, to a spontaneous activity, implanted in life itself, and analogous to that which is witnessed in the development of an individual organism, from the primitive cell up to the final complete development” (Montessori 1913: 46). Methodologically, the key move here is the suggestion that there is an analogy between the development of individual organisms and evolution of species. Substantively, this leads to a focus on internal drivers of evolutionary development. To some extent, this aspect of Montessori’s position is already implicit in Darwin and has now become standard biological orthodoxy. Natural selection operates only in the context of given variations, so environment can only drive evolution if there is an antecedent cause of sufficient variations of the right kind. Nailing down exactly what causes those variations remains an important problem within contemporary biology, though the discovery of DNA and its operations (and “errors”) has provided a framework for answering that problem. During the early twentieth century, however, Darwin’s unexplained source of variation invited metaphysically loaded accounts of variation, and Montessori offers just such a conception. The universe is teleologically ordered towards the “progress and perfectionment” of living creatures, both as individuals and as species (Montessori 1913: 46–47): “a great universal power . . . is the force of life itself in the process of evolution. It drives every form of life irresistibly towards evolution, and from it come the impulses to action. But evolution does not occur by luck, or by chance, but is governed by fixed laws” (Montessori 1988/1949: 230).

Not only does embryology provide an analogy for understanding macroevolution, both embryology and the evolution based on it provide a basis for understanding *psychological* development. The “spiritual embryo” is “the newborn child [who] has to do a piece of formative

work which corresponds in the psychological sphere to the one just done by the embryo in the physical sphere” (Montessori 1988/1949: 55). Montessori’s emphasis on this “spiritual embryo,” and particularly on the development of children in early infancy, gave her a distinctive perspective on the role of the unconscious in human development. Like Sigmund Freud, Montessori saw the unconscious as an important force in the formation of human personality and even as a driving factor in history (see especially “The Unconscious in History”, Montessori 2012/1948). Unlike Freud, however, Montessori approached the unconscious from the standpoint of a pedagogue constantly engaging with very young children. Rather than “probing the ills of a diseased mind” and making inferences about unconscious influences in a way that is “limited . . . to the study of pathological cases” and “abnormal states,” Montessori develops a method of “observation” of children “from a psychic point of view,” directly grasping unconscious “realities of human life mirrored in the soul of a child” (Montessori 1966: 9, 11). As with Freud, she emphasizes the dangers of various repressions and complexes (e.g., Montessori 1966: 10, 154–176), though for Montessori the most important repressions are not sexual but rather repressions of the child’s desire for freely chosen work. Her conception of the unconscious includes and expands on Freudian accounts of the unconscious and also includes what has recently been called the “adaptive unconscious” (Wilson 2002). She drew from the educationalist Percy Nunn the concepts of “*horme*” and “*Mneme*,” referring to the unconscious correlates of volition and memory (or cognition). *Horme* consists of a “vital force” or “guiding instinct” that “takes the form of a drive towards an ever greater independence,” such that “if we tried to find something resembling this *horme* in conscious life, it might be likened to will-power[, b]ut this would be an extremely poor analogy [because] the idea of will is too restricted, too much a part of a person’s awareness” (Montessori 1988/1949: 76; Montessori 1966: 199–206; cf. Nunn 1920: 23). *Mneme* is that “vital kind of memory, which does not consciously remember, but absorbs images

into the individual's very life" (Montessori 1988/1949: 56–57).

Beyond the general notion that early development is akin to a spiritual embryology, Montessori draws several specific theoretical guideposts for developmental psychology from early embryology and evolutionary theory. One of the most important features of Montessori's pedagogy, one that Rita Kramer credits Montessori as inventing, is the "sensitive period" (what is now typically called a "critical period") in development (Kramer 1976: 373–374; See too Lillard 2005: 122–26). Montessori herself credits this idea to deVries and the embryologist Charles Manning Child (Montessori 1988/1949: 94; Montessori 1993/1948: 76). Her discussion of the latter is particularly illuminating for seeing the connections between embryology, evolution, and developmental psychology. She explains,

It is clear that nature follows a plan, which is the same for atom as for planet. It was in 1924 that the embryologist Child revealed those points of febrile activity called Physiological Gradients, not all starting together, or with the same intensity, but each with its own tempo, pursuing an independent course. To begin with, the unit cells were exactly like all the others, but through their activity they grew to differ and became specialized, for the formation of an organ, and last came the circulatory and nervous systems to link the organ with others, similarly created in independence, but to a different functional end.

These are found to be the basic principles of nature's plan:

1. The freedom and independence of organs in their several developments.
2. Development through specialization of cells.
3. The unification of organs by the circulatory system of the blood.
4. Directive communication established by the nervous system. (Montessori 1993/1948: 76)

Montessori uses these fundamental principles to understand the overall development of natural systems, from atoms and planets through organisms and even "the different centers of civilization [that] have been nursed to strength in isolation [and] then brought into contact" (Montessori 1993/1948: 77). She also uses the specific patterns of embryological development, from sensitive periods to a tendency for fine-grained specialization rather than generic function, as models for

psychological development. Just as we develop different organs for different purposes, and these develop in isolation before being united systematically, so too we develop different psychological structures for different specialized tasks, and these then become integrated into a coherent personality.

In her *Pedagogical Anthropology*, Montessori makes a similar point about the "transformation" that

is not that of a succession of very gradual variations . . . On the contrary, what produces stable characteristics is a *revolution* prepared in a latent state, but unannounced in its final disclosure. A parallel to this is to be found, for example, in the phenomenon of puberty in its relation to the evolution of the individual. (Montessori 1913/1910: 47)

Evolution of biological structures, psychological traits, and even species proceeds through independent cultivation of parts that unite into integrated wholes, and each aspect of this evolution occurs in sudden bursts punctuated by long periods of preparation.

Strikingly, this quotation from the *Pedagogical Anthropology* also reflects a return from embryology and individual psychology back to macroevolution. Montessori brings up deVries's account of sensitive periods and even the comparison to puberty in order to make a broader point about evolutionary processes, that "new species are formed . . . through spontaneous activity" in a way that is "expected" and "not . . . gradual" (Montessori 1913/1910: 47). While the specific example she cites from deVries (the plant "*Enohtera Lamarckiana*") has proven to be problematic, the conception of sensitive periods of development, particularly in the more detailed accounts given by Manning and deVries, suggested to Montessori and deVries something like what has come to be called "punctuated equilibrium" (see Gould 2007); that is, with respect to the evolution of species, "it became possible to envision other possibilities than that of the slow adaptive transformations of the Darwinian hypothesis, which required immense periods of time" (Montessori 1988/1949: 49). For Montessori, the evolution of species, like the development of biological structures in embryos and

psychological structures in human children, involved long periods of latent development and then sudden eruptions as new potentialities become realized.

Evolution, Ecology, and the “Cosmic Plan”

Before turning to her discussion of empirical psychology in particular, two further features of Montessori’s evolutionary theory are important to mention. First, Montessori strongly resisted the individualist versions of Darwinism – popularized most prominently by Herbert Spencer – that insisted on a competitive struggle and the “survival of the fittest.” Instead, under the influence of Louis Bourgeois and other solidarists in France, her approach to evolution emphasized the role of cooperation in evolutionary success (see Frierson 2018). This gave her evolutionary theory a distinctly ecological focus, a point she makes explicit in her *Absorbent Mind*:

Ecology is a study of the different behaviors of animals, and it reveals that they are not here to compete with each other, but to carry out an enormous work serving the harmonious upkeep of the earth . . . Behavior does not merely fulfil the desire to continue to live. It serves a task which evidently remains unknown and unconscious to the being . . . If animals were to become self-conscious, they would be conscious of their habits, of the beauty of the places in which they live, but certainly the corals would never realize or understand that they are the builders of the world, nor would the worms which fertilize the earth consider themselves agriculturists, nor would others consider themselves the purifiers of the environment and so forth. The purpose which places the animals in relation to the earth and its upkeep would never enter their consciousness. Yet life and its relation with the surface of the earth, the purity of the air, the purity of water are dependent upon these tasks. So there is another force which is not the force of the desire for survival, but a force which harmonizes all the tasks. Let us say that each one is important . . . because it carries out tasks which are useful to the whole and the effort of each is to try and reach the place allotted to it and the task which it is to fulfil. (Montessori 1949: 89–90)

As she puts it in her discussion of the elementary science curriculum:

One side of evolution deals with the satisfaction of vital needs, defense, survival of the species, and growth by modifications towards individual and species perfection. Another – and stronger – factor in evolutionary processes is concerned with the cosmic function of each living being, and even of inanimate natural objects, working in collaboration for the fulfillment of the Purpose of Life in the whole . . . The bee who robs the flower of its nectar is aware only of his own need or the hive’s, not that the flower’s need of his visit is as great for its purpose of reproduction, for perpetuating the life of the species. (Montessori 1993/1948: 26–27)

For Montessori, evolution involves not only the survival of the fittest and the development of species but also the increased harmony and mutual benefit of the ecosystems as a whole.

This ecological emphasis shows up throughout Montessori’s evolutionary theory. For example, her approach to adaptation, she explains that “Adaptation to the environment is necessary for all living creatures” (Montessori 2012/1946: 80) but then conceives of that adaptation not in the purely individual terms of the “old idea . . . that we lived in the environment and absorbed as . . . much as possible for ourselves from the environment” but as a process whereby “[e]ach species’ adaptation to the environment shows us what the purpose and useful work of each is, the work which each contributes towards universal harmony” (Montessori 2012/1946: 87–88). Biology cannot be limited to the study of “those things that each species does for the maintenance of its life” but must also include “the important work which is done by each species individually for the harmony of all” (Montessori 2012/1946: 84).

These passages emphasizing the ecological dimension of Montessori’s evolutionary theory already hint at her deeper teleological conception of the “cosmic plan” that all life promotes. In the passage above from the *Absorbent Mind*, not only does she refer to the “force which harmonizes all the tasks,” but the passage goes on:

That is why we said that there was a pre-established plan . . . that . . . puts the animals in relation with the task that they have to accomplish upon the earth. Nor is the [only] purpose of life to perfect oneself, nor only to evolve. The purpose of life is to obey the hidden command which ensures harmony among all and creates an ever better world. We are not created only to enjoy the world, we are created in

order to evolve the cosmos. Today the influence of the existence of a cosmic plan is gradually changing the theory of the linear evolution of past times. (Montessori 1949: 89–90)

In *To Educate the Human Potential*, she explains, “Plant life and animal alike now have to be considered from two points of view, and the more important is that of their function in the cosmic plan” (Montessori 1993/1948: 26). References to this cosmic plan, a teleological ordering of the universe towards increases in harmonious complexity, pervade Montessori’s writings (for discussion, see Frierson 2018).

This teleological, ecological approach to evolutionary theory plays central roles in Montessori’s approaches to both psychology and pedagogy. For one thing, Montessori sees psychology itself – the set of psychological forces at work in human beings – as a stage in the increased complexity of the universe, one that serves to harmonize increasingly complex biological forces into a new – “supranatural” – level of organization (Montessori 2012/1948: 23–24). Moreover, insofar as children’s psychological development is a part of this “cosmic plan,” it too proceeds in accordance with laws of life that have a teleological orientation towards the good of the whole.

There are some immediate implications of her overall conception of evolution for pedagogy, most notably in the series of lessons that make up elementary curricula (particularly the “Great Lessons”). Montessori claims that “When details are presented as being parts of a whole, they become interesting” (Montessori 2007/1948: 20). Thus, her elementary curriculum involves a “study of the whole” (Montessori 1993/1948: 23), a series of stories of the evolution of the universe, life on earth, and the development of human societies. Her conception of the cosmic plan affects the structure of these lessons in the development of life and of human societies. But these direct influences on her lessons are less important than two other crucial implications of her evolutionary theory for pedagogy. First, since children’s development is teleologically driven, the function of education is to provide room for psychological expansion, not to generate or stifle such expansion:

By education must be understood the active help given to the normal expansion of the life of the child. The child is a body which grows, and a soul which develops – these two forms, physiological and psychic, have one eternal font, life itself. We must neither mar nor stifle the mysterious powers which lie within these two forms of growth, but we must await from them the manifestations which we know will succeed one another. (Montessori 1912/1909: 59)

Second, because humans’ cosmic task is an ecological task, and because humans are capable (in ways that other animals are not) of becoming self-consciously aware of that task, one of the central functions of education, particularly for elementary and adolescent children, is to help them orient their immense energies in terms of their place in social and ecological systems of interdependence. Thus, the great lessons that “present . . . the world” (Montessori 1993/1948: 20) also show students how they can contribute to the development of societies and the world; students’ imaginations are fostered through thinking about their place in the great “cosmic plan.”

Scientific Pedagogy

Thus far, I have focused on Montessori’s theory of evolution, but Montessori was an experimental psychologist more than a theoretician of evolution. Her theoretical evolutionary framework supports and is supported by her experimental work; thus, she looks for – and finds – evidence of sensitive periods and the sudden consolidation of organized psychological structures. But her approach to psychology was essentially empirical rather than theoretical. In her *Pedagogical Anthropology*, she strongly endorses her mentor Sergi’s focus on “the human individual taken from actual life, in place of general principles or abstract philosophical ideas” (Montessori 1913: 14), and in her *Montessori Method*, she insists that the basis of a “scientific educational program” must not be mere philosophical conjecture (as in Rousseau) but “the *observation* of free children” (Montessori 1912/1909: 28). Roughly speaking, Montessori endorses Wilhelm Wundt’s “definition” according to which “all methods of

experimental psychology may be reduced to one, namely, carefully recorded observation of the subject” (Montessori 1912/1909: 72–73), but she rejects widespread positivist psychological theories from Fechner and Wundt to her contemporaries, arguing that they are “arbitrary and superficial” (Montessori 1991/1918: 86) and exhibit a tendency in “experimental psychology” to “adopt . . . more or less the standard of laboratories of *physics*” (Montessori 1991/1918: 98).

Montessori’s criticisms of the experimental psychology of her day can be summarized under roughly four basic headings (see Frierson 2015). First, she criticized experimental psychology for being too disengaged and strongly rejected the ideal of merely “objective” and even “blind” inquiry into human mental life:

As long as ‘science’ limited itself to the attaining of further knowledge about children without attempting to rescue them from the many evils which this same science had discovered in the schools . . . , no real claim could be made for any such thing as ‘scientific education.’ (Montessori 1967: 41)

In place of an objectivist model of scientific inquiry, Montessori embraced a broadly Jamesian, pragmatic conception of the search for truth; as she put it, “the *soul of the scientist* is entirely possessed by a passionate interest in what he sees. He who has been ‘trained’ to see, begins to feel interest, and such interest is the motive-power which creates the spirit of the scientist” (Montessori 1991/1918: 102). Second, against approaches to experimental psychology that focus on snapshots of human behavior or childhood development, Montessori argued that one must see the unfolding of the life of the child through extensive observation conducted over long time horizons:

The study of the child cannot be accomplished by an ‘instantaneous’ process; his characteristics can only be illustrated cinematographically . . . [T]he psychologist of today behaves somewhat like the child who catches a butterfly in flight, observes it for a second and then lets it fly away again . . . (Montessori 1991/1918: 86, 99)

[P]sychical researches of a moral order must also, if they are to be of any real value, be based upon prolonged observation . . . [I]t is necessary . . . to observe . . . for a considerable time. (Montessori 1967: 8–9)

Third, Montessori objected to a tendency in experimental psychology to “adopt . . . more or less the standard of laboratories of *physics*” (Montessori 1991/1918: 98), a tendency evident not only in crudely materialist conceptions of mind but also in the sorts of quantitative techniques wrongly – and often absurdly – applied to the investigation of human behavior and mentality. Fourth and finally, Montessori argued that contemporary psychologists studied human beings in a defective and unnatural condition, so that rather than seeing normal human psychology, theories were developed that treated common pathologies of modern life as though they were the normal condition of humanity. She compares the study of children in ordinary schools, where they are “repressed in the spontaneous expression of their personality till they are almost like dead beings” to the attempt to discern the nature of butterflies by their behavior when “mounted by means of pins, their outspread wings motionless” (Montessori 1912/1909: 14). Instead, Montessori insists upon providing a condition within which children can behave in accordance with their natural impulses and latent potentialities. In such contexts, she discovered what came to be called “New Children” (see Radice 1920) and what Montessori herself describes as “normalized” children:

Experience has shown that normalization causes the disappearance of many childish traits, not only those which are considered to be defects but also others which are generally thought to be virtues . . . They also include traits which have been scientifically studied and identified with childhood, such as imitation, curiosity, inconstancy, and wavering attention. The disappearance of these childish characteristics shows that the true nature of a child has hitherto not been understood. (Montessori 1966: 154)

Insofar as psychologists take disinterested snapshots of children (or even adults) in unnatural conditions of development, applying quantitative standards of physics to those snapshots, they will never truly understand human nature and its potentialities.

Montessori’s critiques of experimental psychology paved the way for her own conception of the “teacher-scientist,” who would genuinely love her students (avoiding disinterest), stay with

them for long periods of time over prolonged periods of their development, investigate their development using qualitative measures appropriate to human lives, and work with children in an environment prepared to provide occasions for free activity (rather than inactivity and the repression of their innate tendencies). Mere scientists fail to have the interest and engagement to properly observe children's development, but most teachers are not well trained in scientific praxis. The details of this alternative Montessori vision are laid out in much more detail in Montessori's works (see especially 1912/1909, and see too Frierson 2015), but her basic call is for "a genuine fusion of . . . modern tendencies, in practice and thought; such a fusion as shall bring scientists directly into the important field of the school and at the same time raise teachers from the inferior intellectual level to which they are limited today" (Montessori 1912/1909: 4). Or as she puts it later, "the attitude of the teacher should be at once positive, scientific, and spiritual" (Montessori 1991/1918: 106–107).

Conclusion

Montessori's evolutionary theory was heavily informed by the biological-embryological work of deVries, Naegeli, and Child, the philosophy of William James, Hegel, and Nietzsche, and her own observations of the development of children. The result was an evolutionary theory according to which nature as a whole, individual species, and individual members of species all pursue increased "perfection," understood as an increase in agency and organized complexity. This development happens in a teleologically ordered but discontinuous way, organized around particular sensitive periods within which certain new capacities emerge. Human psychology fits within the broader processes of cosmic evolution as the most recent and most complex source of developmental laws, and it has its own structures of development oriented around "vital impulses" that are actualized during particular sensitive periods in the development of each person. These developments – psychological as

well as evolutionary – are never *merely* for the sake of individual organisms or species, however. As we develop, we do so for the sake of our "cosmic task," to fulfill our role in the unfolding development of the world as a whole. This evolutionary theory was refined in the context of Montessori's careful observation of the development of children, particularly the "spiritual embryos" that during the first 6 years of life are forming their personalities and characters. In turn, her conception of development as motivated by guiding instincts, sensitive periods of development, and an overall tendency towards adaptation that would contribute to a cosmic (ecological) plan fostered Montessori's attention to the innate potentialities of children and the method of freely chosen work as central to proper pedagogy.

[Aggression](#); [Competition](#); [Homicide](#); [Young male syndrome](#)

Definition

Males compete for access to female parental investment. Males in long-term relationships have less to gain from that competition, whereas males without ready mating access have much to gain and little to lose. This provides an explanation for why young, unmarried men are the primary perpetrators of violent and deadly aggression.

Introduction

Reproductive fitness is the primary unit of success in the evolutionary game of life. Limited resources and mating opportunities lead to intense competition where the winners successfully pass on their genes to the next generation and the losers face reproductive oblivion. Given the high stakes, it should not be surprising that competition over members of the opposite sex has resulted in violent and deadly encounters. The main participants in these acts of violence tend to be young unmarried men looking to gain respect and resources to improve their reproductive opportunities (Daly and Wilson 1988). This has led to a large disparity between men and women, and also unmarried and married men, in the rates of perpetration of violent crimes. This entry provides an evolutionary explanation for why younger, unmarried men are more violent than married men.

Evolutionary Background

Owing to their reproductive physiology, women invest a significant amount of time and energy to ensure the wellbeing of their offspring from conception to birth, and thereafter (Trivers 1972). In comparison, males' obligatory investment is quite minimal. Given this discrepancy, female parental investment is the resource that limits male fitness and subsequently ignites competition between male rivals. This often takes the form of competition over men's status within a group, their access to resources, and direct mating access. Indeed, men compete for the means to attract mating opportunities and deter rivals (Wilson and Daly 1985). A male's ability to deter rivals may increase his fitness and will ensure that his genes are passed on to the next generation and also lower the fitness of his rivals.

This competition among men is escalated by the fact that many societies are polygamous. According to the ethnographic atlas, out of 849 societies and clusters in Africa, East Eurasia, North America, South America, The Insular Pacific, and the Circum-Mediterranean, 83% practice polygamy (Murdock 1967). This social

structure is a luxury only for men of high social rank. In the demographic survey of the Xavante Indians of Brazil, 40% of married men were polygamous and the rest of the adult men were unmarried. In contrast, no woman of fertile age was without a husband. By age 20, only 1 out of 195 women had not given birth, whereas 6% of men who reached 40 years of age were still childless (Salzano et al. 1967). Muley Ismail, emperor of Morocco, had a harem of 500 concubines. Harems are common in ecologies where it is possible for one or a few men to accumulate vast wealth, and have been documented in Asia, the Middle-East, and sub-Saharan Africa (Betzig 1982). The result of this structure is that only a few men enjoy reproductive success, and the rest face the potential of reproductive oblivion. This incentivizes intense and sometimes deadly competition among men.

Patterns of Violence

Wilson and Daly (1985) reported on a landmark study examining predictors of homicides in Detroit in 1972. The study revealed a pattern of violence supporting the theorizing that most homicides are motivated by competition for status among men.

Wilson and Daly (1985) described two different types of homicide: “crime specific” and “social conflict.” Both terms were coined by Wilt (1974) who examined the 512 closed homicide cases in Detroit in 1972. Crime-specific homicides are cases where homicide was the unintentional result of another crime (e.g., robbery) where the offender did not initially intend on killing the victim. Social conflict homicides are described as heat of the moment actions taken by the offender and not incidental to the omission of another crime. Two-thirds of the 512 closed homicide cases in Detroit were declared social conflict cases (Daly and Wilson 1988).

More than half of the social conflict homicides between nonrelatives were described as “escalated showing off disputes” (e.g., one-upping somebody) and “disputes arising from retaliation for previous verbal or physical abuse” (e.g.,

insulting somebody) (Wilson and Daly 1985). Social conflict homicides are a struggle for status and respect, or in other words, social resources that are valued by men because of their positive fitness consequences. The more respect and social resources you have, the better chance you have at attracting the opposite sex (Wilson and Daly 1985). This makes men more inclined than women to participate in risky competitions to increase status (Weinberg and Ragan 1980). Additionally, participants in these two types of crimes are typically *young* men. In Detroit in 1972, the age group with the most homicide victims was 20–24, while the 25–29 age group had the most homicide offenders (Wilson and Daly 1985).

Men more violent than women. The fact that men are willing to use violence as a means to acquire resources is consistent with evolutionary theorizing. Out of 512 homicide cases in Detroit in 1972, only 90 of them (17.6%) were committed by women (Wilson and Daly 1985). In crime-specific cases, males represent 95% of the 134 perpetrators; in social conflict cases, they represent 75% of 337 offenders (Wilson and Daly 1985). Males were also the perpetrators in 93% of robberies, 94% of burglaries, and 91% of motor vehicle thefts in 1981 (Wilson and Daly 1985). These findings are consistent with the notion that men are more willing to tolerate risk than are women, particularly when resources that could improve one’s reproductive fitness are at stake (Wilson and Daly 1985).

Married versus unmarried men. Across social conflict and crime-specific cases, 73% of offenders and 69% of victims were unmarried compared to 43% of same age men in Detroit (Wilson and Daly 1985). Out of the 134 crime-specific cases, 76% of the men involved were unmarried; out of the 337 social conflict homicides, 58% of the males involved were unmarried (Wilson and Daly 1985). Married men may be less violent than unmarried men for multiple reasons. One reason is that they are typically older. Men are the most violent in young adulthood, a life stage where competition for status, resources, and marriageability is most intense (Daly and Wilson 1988). Married men may also be less violent because they already have mating

access to a reproductive partner, this makes the need to collect resources to attract other mates less urgent. Indeed, married men are more likely to have offspring already, and their energy may therefore be diverted to parenting rather than mating.

In contrast, unmarried men are more likely to be faced with intense competition for a limited number of unpaired females, particularly in polygamous societies. Competition for females will be fiercest at the bottom of the scale where the male on track for total reproductive failure has nothing to lose, and will therefore resort to violent tactics to improve his mating prospects (Daly and Wilson 1988). This may lead unmarried males to commit crimes, such as robbery, to gain the resources necessary to increase status, improve their appeal to females, and deter rivals.

Conclusion

Reproductive success is determined by the ability to gain access to mating opportunities. Given systems of polygamous mating and the ability of some men to monopolize a large share of available females, some men face the prospect of reproductive oblivion. This produces intense competition among men for mating opportunities. The competition for resources and mating opportunities is most fierce among young, unmarried, males. Compared to married men, unmarried men are more violent and have less to lose by resorting to violence as a means to gain resources and status.

Marital Status and Infanticide

Christina M. Carolus¹ and Erik Ringen²

¹Department of Anthropology, Yale University, New Haven, CT, USA

²Emory University, Atlanta, GA, USA

Synonyms

[Child homicide](#); [Filicide](#); [Neonaticide](#)

Definition

This entry concerns the relationship between an individual's marital status (e.g., unmarried, married, widowed) and the intentional killing of infant offspring. While infanticide (the killing of children up to 2 years of age) is sometimes treated separately from neonaticide (the killing of

newborns within the first 24 h of birth), both phenomena are considered.

Introduction

Contemporary evolutionary approaches to infanticide emphasize a life history perspective. Life history theory assumes that individuals will exhibit behaviors that, on average and subject to constraints, maximize their lifetime reproductive success and that of their progeny while minimizing energetic costs (Clutton-Brock 1991; Stearns 1992). Life history theory emphasizes *tradeoffs*; for instance, between quality and quantity of offspring, between current and future reproduction, or between somatic maintenance and reproduction. Parental investment theory is a subset of life history theory that considers how parents optimally allocate resources toward offspring (Trivers 1972). Scholars have applied this lens to human parental investment by examining modulation of investment in relation to socioecological factors and offspring quality (Hrdy 1992; Lawson and Mulder 2016; Minocher and Sommer 2016).

Infanticide, when committed by a parent, constitutes a complete termination of parental investment. A life history approach aims to identify and explain the conditions under which attenuation or termination of parental investment is expected to yield a net fitness benefit to the parent. From this perspective, marital status is expected to influence investment decisions whenever marriage influences the relative costs and benefits of reproduction and investment behavior (for instance, when marriage entails significant material and social support or grants social legitimacy to both parents and children).

Historical Records

Historical accounts suggest that infanticide is recurrent across time and space. They also suggest that consistent demographic similarities exist among individuals who commit infanticide. Resnick's (1970) review of worldwide infanticide records from the seventeenth to twentieth

centuries found that most infanticides were committed by mothers, and that these mothers tended to be young and unmarried. Moreover, he concludes that most were not suffering from mental illness at the time of the infanticides, suggesting that the behavior is not necessarily pathological. Among married women, the most commonly cited motivation for killing newborns was extra-marital paternity, whereas the most common motivation for unmarried women was to avoid the negative social consequences of an illegitimate birth. Resnick also notes that killing of infants rather than neonates tended to be done by older mothers whose motivation was to end some real or perceived suffering (e.g., deformed or sickly infants). This bimodal distribution of behaviors suggests that the relationship between infanticide and marital status is contingent not only upon social legitimacy concerns but also broadly upon factors such as maternal age and infant quality.

In her review of infanticide in Western history, Moseley (1985) similarly concludes that infanticide is generally committed by mothers for "social or economic" reasons (although infanticide threat by fathers was reportedly high during Greco-Roman times, as paternal filicide was legally allowed). Daughters were often perceived as an economic liability among poor feudal farmers. In combination with pervasive androcentric ideology, this led to a disproportionately high rate of female infanticide over the course of Western history. Moseley notes that marital status in the Middle Ages modulated acceptability of infanticidal behaviors: unmarried women were harshly punished for committing infanticide, while married women could kill their infants with "relative impunity." Certain individuals (in this case, married women) were therefore permitted greater control over their reproductive and investment decisions because their offspring were regarded as "legitimate."

Moseley concludes that the decline of infanticide in Europe was linked to both greater financial stability among the poor and an increased availability of breastfeeding alternatives (e.g., animal milk, artificial formula), which reduced the energetic burden of childrearing. Daly and Wilson (1988) credit the historical fall in English

infanticide rates to improvements in social welfare services, access to contraception and legal abortions, and the declining social stigma attached to unmarried mothers.

Contemporary Cross-National Patterns

Drawing statistical inferences from infanticide data is complicated by underreporting, inconsistency in government records (Porter and Gavin 2010), and the relative rarity of the phenomenon. Despite this limitation, records from law enforcement and other government agencies have been used to assess broad patterns of infanticide among industrialized nations during the twentieth and twenty-first centuries. Across nations such as the United States (Overpeck et al. 1998; Oberman 2001), Canada (Daly and Wilson 1988), Italy (Ciani and Fontanesi 2012), Croatia (Marcikić et al. 2006), and Malaysia (Razali et al. 2014), most infanticides are committed by the mother of the infant, many of whom are unmarried or partnerless. In their study of Japanese infanticide, Sakuta and Saito (1981) describe two distinct modes of infanticidal behavior: *anomie*, in which infants are killed by relatively young, unmarried parents (typically mothers), and *mabiki*, in which the parents are married and already have children but cannot afford to raise additional offspring. These patterns parallel the difference that Resnick observed between infanticidal behavior by older, married women and younger, unmarried women in historical cases.

Detailed data regarding infanticide in developing nations are scarce. However, the available evidence suggests that general patterns are similar to those seen in developed nations. In South Africa, young mothers are the most common agents of infanticide, but no information is reported regarding marital status (Abrahams et al. 2016). Interviews with couples in Tamil Nadu, India have revealed that most parents considering infanticide are young (between 20 and 30 years of age), are relatively poor, and already have at least one other child (Giriraj 2004, cited in Tandon and Sharma 2006). This cluster of traits suggests that resource stress exerts notable influence upon parental investment. Though more data are

needed, resource stress may prove powerful enough to drive investment and termination decisions independent of marital status.

It is also worthy to note that cross-national paternal infanticide data displays somewhat different patterns than maternal infanticide data. Paternal killing of neonates (infants aged less than 28 days) is less frequent. Fathers and step-fathers who kill children instead tend to do so when the children are older (West et al. 2009). The demography of infanticidal fathers may, however, parallel that of infanticidal mothers; for instance, in Canada, infanticidal fathers are generally younger (Daly and Wilson 1988).

Patterns in Small-Scale Societies

Small-scale, nonindustrial societies are often objects of scholarly interest because they tend to be *natural fertility* populations, as defined by a lack of access to (or use of) commercial contraceptives. The introduction of commercial contraceptives can significantly alter reproductive behavior. Declining fertility in many industrial nations in recent centuries has been attributed in part to the increased availability of commercial contraceptives, safer abortion procedures, family-planning initiatives, and to changing social norms (Sear et al. 2016). Fertility transitions such as these may shift locally optimal life history and parental investment strategies in ways that are drastic and historically anomalous. Moreover, many contemporary industrialized nations have experienced public health breakthroughs, such as sanitary improvements and development of infectious disease prevention, dramatically reducing infant mortality (Stearns 2016). The potential for both greater reproductive agency and lower infant mortality have serious implications in terms of transforming reproductive behavior and parental investment decisions in human populations. Cross-cultural survey of nonindustrial societies has provided a diverse sample that helps to elucidate the relationship between marital status and infanticide in societies that differ in important ways from industrialized nations.

Daly and Wilson (1984) embraced the cross-cultural approach, surveying ethnographic accounts of infanticide in the Probability Sample Files, a stratified sample of nonindustrial cultures selected from 60 world regions. Of these 60 cultural reports, 39 contained information about infanticide (but note that absence of evidence here is not evidence of absence). Daly and Wilson examined the social context in which infanticide occurred. They found that being an "unwed mother" was a recurrent motivation for committing infanticide. A related motivation, "no male support," was also observed frequently across cultures. In a different cross-cultural study that focused on twin infanticide, mothers were found to be far less likely to kill twins in cultures where they had a high degree of social support (Granzberg 1973).

Culture-specific case studies are also informative. Bugos and McCarthy (1984) describe a similar pattern of infanticide among the Ayoreo of the Gran Chaco region in South America. Some women, due to a lack of guaranteed male support, committed multiple infanticides over the course of their reproductive lives before settling into a stable marriage. Nancy Howell (1979) reported that Dobe !Kung mothers who gave birth before they could safely wean their older children might also opt for infanticide, a possible example of a quantity-quality trade-off. Among the Tarahumara of northwestern Mexico, infanticide may occur when the mother has inadequate male support, when the mother has too many children already, or when the infant is perceived as defective or sickly (Mull and Mull 1987). One of the few detailed, quantitative studies of infanticide in a small-scale society was conducted by Wulf Schiefenhövel among the Eipo, a population of horticulturalists in Highland New Guinea. Schiefenhövel observed an extraordinary rate of infanticide (between 29% and 43%) in a population that he argued was at the limit of its resource base. In interviews with women who committed infanticide, it was determined that extramarital pregnancies, having too many children already, and young maternal age were among the most commonly cited motivations for committing infanticide (Schiefenhövel 1989).

These findings implicate marital status as an important mediator of infanticide, insofar as marital status predicts access to male support, greater material and social resources, and greater social status and acceptance in general. However, there is no single "typical" pattern of infanticide in nonindustrial societies. Investment and termination decisions, as in industrialized nations, are inextricably tied to individualized social and economic concerns and vary based on the support available to mothers.

Conclusion

Cross-cultural and cross-national data are consistent with a life history perspective in which infanticide is most prevalent among (1) young, unmarried mothers who lack sufficient social and material support and (2) among older, married mothers who have insufficient resources to support additional children or who have had extramarital affairs. This relationship between marital status and infanticide is strongly influenced by the levels of social support and material resources available to parents. The comparative evidence is likewise congruent with life history perspectives, which anticipate tradeoffs between current and future offspring and between quantity and quality of offspring. But while infanticidal motivations are similar across time and space, it does not necessarily follow that humans possess adaptations for infanticide per se. As Daly and Wilson emphasized:

The specific act of infanticide may or may not benefit the actor's fitness, whether in an individual case or on average, but the act need not contribute to fitness for a sociobiological analysis to be illuminating. Infanticide can be viewed as one (rare) manifestation of variations in more abstract motivational states such as child-specific parental love and solicitude. Adaptation may then be sought at the level of these more abstract states. (Daly and Wilson 1984)

Patterned relationships between infanticide and marital status can emerge without the need for highly specialized psychological adaptations. A more fruitful approach may be to consider how more generalized parental investment

strategies and life history tradeoffs interact with variable socioecological circumstances and individual differences in reproductive and social status.

[Long-term partnership](#); [Pair bonding](#)

Definition

Marriage is a sociosexual and socially recognized bond of some duration between a man and a woman. This is the traditional definition of marriage, although other sociosexual partnerships may meet the criterion.

Introduction

An evolutionary model of marriage begins with recognition of the centrality of reproduction to the relationship. The economic benefits of marriage, such as economies of scale and specialization of labor, are essentially subordinate to reproduction; raising children is costly in terms of wealth and labor.

Marital behavior that maximizes reproductive success will be favored by natural selection. Marital behavior seems to have evolved in order to keep the parents together and available to raise their common offspring. Infants and children are

highly dependent on their parents and develop better when raised by their biological parents than in most if not all other arrangements. This is true not only of infants but also of children and adolescents and applies to health, psychological functioning, cognitive performance, antisocial behavior, and survival itself (Geary 2005; Cabrera et al. 2000).

The functional hypothesis that marriage evolved mainly in order to promote biparentalism is supported by the fact that pair bonding, the rough animal equivalent, tends to occur in mammals with highly dependent young. In essence, in these species the male tends to remain with his mate rather than pursue other sexual opportunities. However, even in the primates, in which the young are highly dependent on maternal care, pair bonding is the exception rather than the rule. Another factor recognized in the evolution of marriage is the opportunity for effective mate guarding.

Marriage is universal, and almost all adults seek to marry, and most do marry, sometimes more than once. Marriage confers health and emotional benefits on both sexes (Field 2011). People who do not marry tend to fail to attract a partner, such as impoverished men. These facts suggest that adult humans possess what might be called a pair-bonding motive, perhaps best termed amorousness. In a US survey, almost no one not in a romantic relationship renounced seeking such a relationship for any appreciable length of time. Amorousness is distinct from the sex drive, although from puberty on, a sexual component seems invariably to accompany amorous feelings toward the partner. The capacity for amorousness is universal (Jankowiak and Fischer 1992). Even in arranged marriages, amorousness tends to develop afterward, although less often than in self-selected marriages. The evolved basis of amorousness is further supported by the fact that particular brain areas are activated by viewing a photo of the loved one, including the anterior cingulate cortex (Fisher 2006). Brain areas involved in pair bonding tend to have vasopressin or oxytocin receptors; these hormones play a role in pair bonding and parental care in rodents (Bartels and Zeki 2004). Orgasm causes a surge in oxytocin in both sexes that enhances the

bond between them. Relationship satisfaction in women is correlated with oxytocin levels and in men with vasopressin levels (Taylor et al. 2010).

Marriage Rates

The adult sex ratio influences the marriage rate. When men are in short supply, a lower percent of women marry since men can secure sexual opportunities, sometimes with multiple women, without having to marry. When women are scarce, more are able to secure the advantages of marriage for economic security, companionship, and childcare assistance. Under these latter conditions, their marriage rate rises, and the divorce rate falls.

It has been observed that the contemporary African American community suffers from a dearth of marriageable men, with the result that the great majority of children are raised by a single mother, often assisted by her mother. This matriarchal family arrangement is not a carryover from slavery since around World War II when good jobs for black men were abundant, 80 % of adults were married (Harris 1974). Only with the return of white veterans and the subsequent loss of factory jobs for black men did the marriage rate begin its decline. Economic factors more than cultural factors drive marital dynamics.

The marriage rate is low where men have difficulty finding work that allows them to help support a family. A job that allows a man to support only himself generally renders him unmarriageable and raises the likelihood of divorce. The marriage rate in a society tends to be correlated with economic opportunities, particularly for men. Where good jobs for men are scarce, fewer men marry and the age of marriage rises, as men need more time to accumulate sufficient resources and skills to afford marriage. In modern societies with companionate marriage, women's age at marriage tends to track men's, so with the current decline in economic opportunities for young people, men and women are marrying later than in the recent past.

In modern societies with comparatively late marriage, women tend not to be protected against premarital pregnancy by the period of adolescent

subfertility. Hence an adolescent girl can get pregnant and become an unwed young mother, the consequences of which are usually grim for both her and the child. The rate of premarital pregnancy and hence single motherhood is higher in countries such as the USA where confidential, free contraceptive services are not provided in secondary schools.

The marriage rate has been falling in Western societies since the Industrial Revolution. Fewer women are marrying, and more women are divorcing. The main reason seems to be that women's economic opportunities have been rising steadily: salaried jobs are open to them, and they are no longer bound to the family farm (Goode 1993). Many of them can support themselves, and even raise children independently. Cultures in which women and men labor independently tend to have higher divorce rates.

Mate Choice

In most tribal cultures, a man must furnish a bride price or labor in order to procure her from her father. The fact that a man often needs many years in order to acquire the requisite skills or resources helps to explain the fact that husbands tend to be older than their wives across cultures. The age disparity is also explained by the breeding imperative: a woman who is just reaching the onset of fertility is at her maximal reproductive value for a prospective husband. Accordingly, women in tribal societies tend to marry, or be married off, about 2 years after menarche, when the period of adolescent subfertility has just passed. This also ensures that she is unlikely to be pregnant.

The criteria of mate choice show considerable consistency across cultures. Both sexes seek signs of health and genetic quality in a prospective spouse. Physical attractiveness tends to be enhanced not just by signs of health and vigor but also by indications of full reproductive maturation. Masculine men and feminine women tend to be more fertile than less sex-differentiated individuals. Women also seek men who are high in social status, act with self-confidence, exhibit

nonverbal dominance displays, and secure valued resources (reviewed by Weisfeld 1999). Ethologists define dominance as success in fights or in gaining contested resources, and female animals generally seek dominant males. It seems that women also seek a dominant mate.

Spouses tend to be moderately similar genetically. This seems to be achieved by a combination of olfactory and visual cues. The sexes are repelled by olfactory cues that indicate close genetic relatedness (Jacob et al. 2002; Weisfeld et al. 2003). This guards against inbreeding depression effects and enhances the immunocompetence of offspring. Less well known is the phenomenon of sexual imprinting. In many birds and mammals, the offspring imprints on the visual image of the opposite-sex parent and uses this image in seeking a mate at maturity. This mechanism guides the offspring to pursue mates of the right species, gender, and state of maturity. Men and women tend to marry someone who resembles the opposite-sex parent, thus enhancing genetic similarity of spouses. Preference for mates of moderate genetic similarity has been demonstrated in insects, birds, and primates, so it must be generally adaptive. One explanation is that moderate homogamy, or positive assortative mating, preserves combinations of genes that are adaptive in the parents' (and offspring's) environment. Moderate homogamy enhances fertility in humans as well as other species (Rushton 1988).

Another important criterion in mate choice is the apparent commitment of the potential spouse. The resources that a man commands will be of no value to the woman unless they are directed toward her and her children. Likewise, a man may not only squander his resources if his wife is unfaithful; he may wind up aiding a rival. A man may employ a range of tactics to ensure a woman that he is passionately committed to her, including offering gifts, pledging his devotion, and complimenting her extravagantly. A woman may test a man's commitment by deferring sexual involvement, provoking his jealousy, and raising the question of marriage. She can ensure him of her commitment by the unambiguous expedient of having sex with him exclusively. Both sexes may employ various mate guarding tactics to detect cheating by the other, including, nowadays, constant monitoring by cell

phone. The tactics of courtship and marriage may be categorized as self-promotion and disparagement of rivals, evaluation of the potential or actual mate, and retention of the mate.

Marital Satisfaction and Stability

One would expect that these universal criteria of mate choice would, if met, lead to happier and more stable marriages. That is, selection would have favored criteria that led to stable marriages and resulting enhanced fecundity. This seems generally to be the case. Young brides go on to produce more children than older ones. Wealthier men raise more children successfully than do poorer ones. Wealthier men are less likely to divorce and more likely to be polygynous. Couples who are similar tend to stay together.

Analyzing data on scores of cultures, Betzger (1989) identified common reasons cited for a divorce. These included sexual refusal, suspected infertility, husband's cruelty, and wife's infidelity. Other research has pinpointed having a handicapped child, death of a child, sexual dissatisfaction, and rape of the wife. All these factors in divorce make sense in terms of reproductive failure. Furthermore, around the world the more children a couple have, the lower the likelihood of divorce (Goode 1993). Divorce is more likely in marriages without children, and peaks at about 4 years of marriage. The first few years of marriage seem to provide a trial period for deciding to have children or not and for testing fertility with the spouse. After 2 or 3 years of a romantic relationship, the period of intense infatuation has passed, freeing the couple to shift their affection to the newborn. In a sense, the spouses are now kept together by their baby.

Another cross-cultural criterion of mate choice is kindness (Buss 1989). Recent cross-cultural research has shown that lack of kindness is an important factor in marital conflict, along with sexual problems, issues regarding child rearing, disputes about division of labor, and economic difficulties (Dillon et al. 2015). Kindness would seem to be essential for an enduring marital relationship. Similarly, in the same five cultures, it

was found that the spouse making one laugh was correlated with marital satisfaction of both husband and wife, but especially the wife (Weisfeld et al. 2011). Many women seek a mate with a sense of humor, so this criterion seems to be valid in terms of subsequent marital satisfaction. Having a funny husband did not seem to enhance the wife's marital satisfaction because it was a sign of intelligence, however. Mediation analysis revealed that having a funny spouse enhanced the spouse's satisfaction even more by being a sign of kindness, understanding, and dependability.

Developmentally, marital satisfaction tends to decline over time. This does not seem to be related to any adverse emotional effects of having children, at least in collectivist cultures with a thriving extended family (Dillon and Beechler 2010). The probability of divorce declines over time as well. This is one indication that marital satisfaction and marital stability are somewhat independent. This is also the case in cultures that forbid divorce; unhappy couples are forced to remain together.

Sex in Marriage

Sexual satisfaction and sexual frequency are highly correlated with marital satisfaction. In tribal cultures sex is reported to occur nightly except during periods when it is taboo. Sex is usually taboo during menstruation, often taboo during pregnancy, and seldom taboo during lactation. In the absence of contraceptive use, conception typically occurs within 1 year of the onset of coitus. Inter-birth intervals for our species are about 3 years, so women are perennially pregnant or lactating. Breastfeeding typically lasts for about 3 years, with solid food introduced after about 2 years. In simians nursing usually stops when the next pregnancy begins, if it has not already ceased.

Sexual infidelity is associated with low marital and sexual satisfaction, permissive values, low economic status, and opportunities. Men report more infidelity than women, and attractive men with wealth and high testosterone report more infidelity, at least partly because of greater opportunities. In US research, women with low self-

esteem reported more infidelity. In a cross-cultural study, sexual infidelity for both sexes was correlated with low love of the spouse, finding others sexually attractive, and the spouse being unfaithful (Nowak et al. 2014).

Jealousy

Like other valued relationships, pair bonds tend to be defended against interlopers. For example, children tend to show jealousy if their parent favors their sibling (Dillon 2013). Rivalry for parental resources tends to be greater between half-sibling and stepsiblings than full siblings.

Lovers too exhibit sexual and romantic jealousy; mate guarding is typical of pair-bonding species. If in human evolution there had not been at least occasional instances of infidelity, jealousy would not have evolved. Estimates of the frequency of marital infidelity vary but are not insubstantial. Infidelity may raise a husband's reproductive success if he succeeds in fertilizing another woman. Infidelity may benefit a wife if she cuckolds her husband and thus deceives him into caring for a child she has had by a man of greater genetic quality than his or garners resources from her lover. Jealousy in men tends to be evoked by the threat of the wife's sexual infidelity more than by the threat of her desertion; the opposite pattern is more typical of women. Suspected infidelity is the principal cause of homicide around the world.

In a cross-cultural study, both sexes worried about spousal infidelity more if the spouse was attractive (Dillon et al. 2014). Worry was greater when the spouse socialized independently. Individuals who felt possessive about the spouse touched the spouse more. Worry was greater in persons who were themselves unfaithful.

Child Rearing

Since marriage is essentially about reproduction, it seems appropriate to consider child-rearing behavior within marriage. Longitudinal research reveals that when a man marries or becomes a

father, his testosterone level falls, and if he divorces, it rises (Mazur and Michalek 1998). One effect of testosterone is to increase competitive behavior; a married man has less need to compete for mates than before. Similarly, husbands with comparatively low testosterone tend to be more family oriented, whereas those with higher testosterone are more likely to divorce and to earn less money. When a woman becomes pregnant, she and her spouse experience a steady rise in prolactin, one of the several parental hormones (Storey et al. 2000). The higher his prolactin level after the birth, the more nurturant he is, as indicated by emotional responsiveness to a crying baby. Prolactin also suppresses testosterone, resulting in further nurturance.

Pregnant women undergo a rise in at least nine hormones. Several of these, including oxytocin, estrogens, progesterone, and prolactin, enhance maternal bonding and behavior. Prenatal and pubertal hormones contribute to the sex difference in nurturant behavior observed throughout the life span in humans and other primates. Breastfeeding maintains the levels of the lactational hormones prolactin and oxytocin.

Men and women are hormonally disposed to care for their children, but the mechanisms are quite different. Consistent with this, women seem to be closely bound to their infants, whereas men are relatively more attracted to weanlings. When a second child is born, the father is inclined to assume some of the care of the weanling, while the mother attends to the newborn. Some Scandinavian countries provide fathers with their own period of paid paternal care that they can take after the first year or so of parental leave expires. Fathers often take their sons on excursions during this time. Around the world, men specialize in tutoring their sons in subsistence skills, protecting the family, performing tasks with hard and heavy materials, serving as warriors, and providing more resources given that wives devote more time to child rearing and domestic tasks (Mackey 1996). Mothers are the main teachers of girls' subsistence and child-rearing skills.

In every culture, women provide more childcare than men on average. The parents are typically assisted by grandparents, older siblings

especially daughters, other kin, and other women. Some cultures are described not as having the extended family but as having the nuclear family. However, this invariably means that the grandparents do not share the parents' dwelling but do reside nearby in a family compound. Thus the norm for our species is care by the extended family. Bonds of kinship are established and maintained by olfactory cues, kinship terms, social contact, social pressure, and other factors. In addition, adolescents undergo a period of intense tutoring by a same-sex adult. This instruction pertains to social and tribal obligations and often culminates in a puberty rites ceremony. Children also learn from imitating and being instructed by older children in these cultures characterized by little age segregation.

Divorce typically reduces contact time with the father markedly and imposes financial loss due to the need for separate residences and other appurtenances for the ex-spouses. Children of divorce are essentially raised by a single parent in terms of average developmental outcomes. If the mother remarries, the consequences for her children are often no better than if she remains unattached. Stepchildren are at risk for neglect, abuse including sexual abuse, and even homicide and accidental death. In a US study, only about half of stepfathers and one-fourth of stepmothers reported any parental feelings toward their stepchildren (Duberman 1975).

Cultural Factors

What has been presented thus far is an overview of human marriage – the normative pattern for our species. But human behavior is very flexible, and marriage takes somewhat different forms around the world. In most modern societies and in tribal societies where little property is available for bride price, marriages are usually not arranged by parents – although parents seem to exert considerable influence over children's choices. In these cultures a formal marriage ceremony is especially common, perhaps as a way of displaying wealth, discouraging divorce after a public commitment, and arranging economic

alliances with in-laws. Marriage ceremonies occur in the great majority of cultures (Quale 1988). In all cultures the double standard of less acceptance of female promiscuity than male promiscuity is in evidence to some degree. In some cultures sex roles are strictly prescribed, whereas in modern societies these are being mitigated. However, even in modern societies, men gravitate toward jobs involving hard manual labor and women toward service occupations. Cultures vary in the status ascribed to women compared with men. In most cultures, especially bellicose ones, women are expected to defer to men in various ways, and sons are privileged over daughters. Other societies are more egalitarian, and women live much longer than men, unlike “male supremacy” cultures, where the gap is smaller. In most cultures a man must qualify for marriage economically. Among wealthy people in highly stratified societies, a woman’s family may offer her a dowry to enhance her marriage prospects for marrying into another wealthy family. She will also be pressured to remain a virgin until marriage, as a way of raising her mate value and of discouraging her from eloping with a penurious cad. For an analysis of marriage systems, in particular subsistence conditions, see Quale (1988).

One particularly interesting variant is polygyny. This was permitted in the majority of tribal societies, although only a handful of men could afford more than one wife. Highly stratified societies, such as the USA, effectively have serial polygyny when wealthy men divorce and remarry to found another family. Polygyny increases the reproductive fitness of the husband, but at the expense of men left unmarried. Women with co-wives have almost the same fecundity as monogamous wives, and certainly have more children than unmarried women. The availability of the polygyny option seems to benefit women; they may choose to marry a wealthy man who is already married, rather than marrying a destitute man or remaining unmarried.

Polygyny is favored in economically stratified tribal societies. It becomes more common when the sex ratio falls, as after a war: a defeat brings a shortage of able-bodied men; a victory offers women to be captured. Polygyny is also favored

by poor economic opportunities for women, who must marry for a livelihood.

Polygyny has some advantages, cited by its defenders. It raises the marriage rate for women and the percentage of children brought up by their biological parents. Co-wives can cooperate in various ways, such as childcare and conspiring against the husband. Co-wives are often sisters; if so, child survival is higher. A young wife may be favored sexually by the husband, but first wives tend to have more power.

Conclusion

The field of marriage research has been largely atheoretical. Factual data abound, but conceptual integration of these data has been lacking. Many studies deal only with a single society, particularly the USA. Some standard facts are trivial, such as that spouses tend to have lived near each other before marriage and that spouses tend to have similar values. Until fairly recently, most research on marriage surveyed only the wife. None of the commonly used measures of marital satisfaction has been validated by invariance testing for cross-cultural use. Only the Marriage and Relationship Questionnaire (MARQ) developed in England by Russell and Wells (1993) seems to have had scales validated across cultures and genders (Lucas et al. 2008).

The emerging evolutionary approach to the topic of marriage has offered some distinct advantages. The fraught topic of sex differences in married people has been addressed seriously for the first time. Previously, husbands and wives have been treated largely as interchangeable parts. Similarly, much of the social science literature neglects the factor of kinship. Huge effects of stepparenthood have been disclosed by evolutionary scholars. Unfortunately, the US Census Bureau does not inquire about biological parenthood in its surveys of households.

Evolutionary psychologists have been somewhat slow off the mark in studying marriage. In a way, married couples have been victims of the success of the field in studying mate choice. Hundreds of studies have been conducted on mate

choice, many of them on US college students in dating relationships. Conducting research on married adults has been more methodologically challenging. Particularly rare has been ethological research on married couples, along the lines of Weisfeld and Stack (2002), who found that wives gazed longer at the spouse than husbands, whose glances were brief, and wives laughed and smiled more. Also needed is more cross-cultural research, especially on diverse cultures. If, say, a sex difference is found in a variety of cultures, the likelihood of an evolved basis is higher than if it is found only in Western societies. A volume by Weisfeld et al. (*in press*) is intended to address some of these shortcomings.

Another area in need of further work is the emotional basis of various marital behaviors. Mate retention tactics, employed outside and inside marriage, might be analyzed with regard to the emotions involved in execution and the effects on the partner. For example, several emotions seem to be involved in the threat of mate loss; they might be analyzed in detail. The emotion of amorousness is seldom mentioned as being a basic human emotion, yet it seems to qualify as one. Sexual behavior and emotions seem to vary with the likelihood of sperm competition, another topic that has emerged recently.

Also making great contributions to our understanding of marriage is research on the brain and hormones. These findings have the felicitous side effect of helping to dispel the notion, prominent in the social sciences, that social behavior is simply the product of experience and culture. Demonstrating that a particular neural mechanism mediates some marital behavior or capacity is one sort of information confirming the evolved basis of that behavior. Other methods include showing the specific effect of a hormone and establishing that the behavior is universal. Demonstrating that a given behavior has an evolved basis rather than being a product of our domain-general capacities is necessary for delineating human nature. Once a behavior can be shown to have an evolved basis, questions of its function can be addressed.

The great promise of an evolutionary analysis of marriage is that comparative analysis, including analysis of pair bonding in various species, will lead to elucidation of the function of

particular marital behaviors. Function is a unifying concept that can bridge disciplinary boundaries and make common sense of otherwise baffling research findings.

Author Note Michele K. Surbey, Department of Psychology, College of Health Care Sciences, Division of Tropical Health and Medicine, James Cook University, Townsville, QLD 4811, Australia.

I thank Martin Daly for sharing reminiscences of his and Margo's early years. I also collectively thank their colleagues, friends, and students with whose memories, conversations, and publications I have supplemented my own fallible recollections.

Correspondence concerning this article should be addressed to michele.surbey@jcu.edu.au

Definition

Canadian academics whose scholarly contributions and leadership roles in the Human Behavior and Evolution Society and its flagship journal were significant in the emergence of evolutionary psychology.

Introduction

When published in 1859, *On the Origin of Species* received a cool reception in Canada, owing to reservations of the nation's most renowned nineteenth-century scholars, including J. W. Dawson, Principal of McGill College, and D. Wilson, Professor, University College, Toronto (Zeller 1998). The latter, a historian, artist, early archaeologist, and anthropologist coined the term "prehistory" (Trigger 1966). As its first president, he set the University of Toronto on the road to success and international renown. Unlike critiques of Darwin's natural selection theory based wholly on religious grounds, Wilson's complex views included scientific misgivings over the discounting of uniquely human mental qualities in describing the continuity of species (Trigger 1966). It is perhaps somewhat fitting that just over 100 years later, two Canadians, who would be at the forefront of the emerging field of evolutionary psychology, should meet at the University of Toronto, Wilson's greatest legacy. One, coincidentally, would have the same surname. After receiving their Ph.Ds., Drs. Margo Wilson and Martin Daly met at the university in 1974 (Belluz 2009). There they would begin a great academic and personal partnership that would span almost 35 years and help propel and instantiate an evolutionary approach in psychology and behavior not just in Canada but in the USA and abroad.

Margo Wilson: Early Years in Northern Climes

Margo Ings Wilson was born in Winnipeg, Manitoba, on October 1st, 1942 to Edith Helen Ings, a

nurse and daughter of Col. A. Ernest Ings and Clara S. B. Dodge. Before Margo's birth Edith was in England assisting in the war effort. Col. Ings's father had emigrated from Portsmouth, England to Prince Edward Island (P.E.I.) and ran *The Island* newspaper. Clara Dodge's father was a doctor in Halifax, Nova Scotia. Margo's maternal grandfather was originally trained as a barrister, then served in the 104/105th Battalion in WWI, and later held executive positions in a number of PEI utility companies ("Death in Winnipeg" 1944). The Ings family was prosperous and lived in a grand house on the Esplanade in Charlottetown overlooking the water. Margo would not come to know her maternal grandparents, nor their lifestyle, however, as both had died by 1944. By then Edith had returned from the war and was living in Winnipeg with her little daughter and husband, Major Tom Smith.

In 1948, Edith Ings Smith, now widowed, left Winnipeg with 6-year-old Margo and moved to the Gwich'in community of Fort McPherson in the Northwest Territories (Belluz 2009; Krupp and Barclay 2010; Daly 2012; Gaulin and Fessler 2010). Fort McPherson was originally founded in 1840 by the Hudson's Bay Company and called Peel River House. It is located about 65 miles above the Arctic Circle in the Peel River watershed, a place of great natural beauty belonging to indigenous peoples for centuries. As the only medical professional, Edith provided much needed medical care for the local residents, at times even having to do surgery in communication with a doctor from Inuvik via Morse code. Margo went to the little local one-roomed school where she was the only nonindigenous child in attendance. At a young age, Margo began to understand what it was like to be an outsider but, at the same time, showed empathy for those less fortunate. Throughout her life Margo would support and promote "out group" members or those less advantaged (Belluz 2009; Daly 2012). Taken aback by the poverty and inability of the local parents to pay for children's school lunches, to raise money, Margo ran a miniature dogsled to trap muskrats and sell their furs in cooperation with her classmates (Daly 2012; Gaulin and Fessler 2010; Krupp and Barclay 2010).

In 1952, Edith married the Hudson's Bay Company factor, J. E. J. "Jack" Wilson, posted at the fort ("Happenings" 1952), who bought furs from the locals and ran the company store. A kindly, low-key, pipe-smoking man Jack took Margo under his wing, likely offering advice on her fur-trapping enterprise. About a decade earlier, he had provided natural history information about the fur bearing and game species in the Severn area to researchers from the Royal Ontario Museum of Zoology ("Field work" 1940). One wonders if Margo herself had begun studying animal behavior and physiology, while managing her mixed-breed dog team and checking the trap line. In addition, both Edith and Jack were avid readers and possible models for Margo's developing appetite for knowledge and greater understanding. Together, the three Wilsons kept busy, and their minds occupied many dark cold winters and long-lit summers at Fort McPherson.

Margo went to high school in Victoria, B.C., where her mother arranged for her to stay with a family. In 1960, she earned a Queen Elizabeth II Provincial Scholarship and after graduating high school was admitted directly to the University of Alberta in Edmonton. Margo entered the nursing program, but found the restrictions on student nurses, such as having to live in the residence, a 10 p.m. curfew, and prohibitions against male guests and marriage, outdated and intolerable. She dropped out after about 6 months and, according to her, started a bit of a rebellion, as a high proportion of the other women subsequently left and the administration was forced to remove some of the restrictions. Margo switched programs and graduated with a degree in psychology in 1964. She originally intended to become a clinician, but after brief experiences working in an Oregon mental institution, versus an avian embryology lab, she chose a physiological approach (Belluz 2009; Daly 2012). Satisfying both her physiological interests and desire for a milder climate, Margo entered the masters program at the University of California at Davis in 1965 where she worked with Gordon Bermant studying the behavioral endocrinology of chickens and Japanese quail.

After finishing her masters in 1967, Margo won a Commonwealth Scholarship to study at University College, London, England. There she examined the sexual behavior of rhesus monkeys, including the behavioral effects of castration and hormone replacement on males (Michael and Wilson 1974). She and fellow student, Barry Keverne, worked at the Bethlhem Royal Hospital, known as "Bedlam", the oldest mental institution (Belluz 2009). Her supervisor, Richard P. Michael, a psychiatrist, was also an early behavioral endocrinologist. Working doggedly into the night typing her thesis by candlelight, due to power restrictions, Margo completed her Ph.D. in 1972. After earning her degree, Dr. Wilson returned to Canada. She began teaching classes at the University of Toronto as Lecturer (1972–1973) and Visiting Assistant Professor (1973–1975) and cobbled together a research lab without funding. She also sat on a university ethics committee to review proposals for research on nonhuman animals. One day she received an ethics application in person from a recently arrived postdoctoral researcher. His name was Dr. Martin Daly.

Martin Daly: From Toronto to Algeria and Back

James *Martin* Daly was born on November 15, 1944, in Toronto, Ontario. His mother was Ida Simon, the daughter of parents of Ashkenazi Jewish ancestry who immigrated to Canada from Latvia in the early 1900s. Before the first Russian revolution, Martin's maternal grandfather was drafted into the Russian army to tend his unit's horses, but was left behind after being kicked by a horse. Later, in Canada, he worked at a cleaner's pressing pants for a living. Martin's father, James Alexander Daly, was the son of two Irish immigrants. Growing up in Toronto, Martin attended Bennington Heights Elementary School, then York Mills and Don Mills Collegiates. He did especially well in mathematics and won an international mathematics contest award in 1961. After graduating (1962) with an open scholarship, he attended the University of Toronto, obtaining a

B.A. (Honors Psychology) in 1967 and becoming the first in his family to earn a university degree. With his supervisor, Gary Walters, Martin examined the effects of injections of scopolamine on the disruption of memory formation in rats. That same year he married Sandra Fiegehen, whom he had known since high school. They moved to Montreal where she became a teacher, and Martin received an M.A. in psychology at McGill University in 1968 for his thesis on the satiation of hoarding behavior in rats. At McGill, Martin attended a seminar given by Donald Hebb, a highly admired and respected early Canadian psychologist who inspired his students not to just sop up current knowledge but to seek out uncharted academic territories.

Before going to Montreal, Martin had realized that he was far more interested in studying species-specific animal behavior than conducting physiological manipulations. He returned to the University of Toronto for his Ph.D. to work with Jerry A. Hogan, whose ethological perspective he had admired in undergraduate classes (Daly 2015). Hogan transfixed Martin with both his enthusiasm and strong opinions. Martin worked in Hogan's lab, aka the "Chicken House," completing his Ph.D. thesis, *Behavioural development, early experiences, and maternal behaviour in golden hamsters (Mesocricetus auratus)*, in 1971. After studying behavior in the lab, Martin decided to undertake fieldwork to understand how differences in the social behavior of closely related species relate to features of their ecology. He moved to the University of Bristol to work with John H. Crook, the founder of socioecology. Funded by postdoctoral fellowships, Martin undertook research at a French research station in Algeria, where Sandra assisted with the field research on the feeding behavior and socioecology of Saharan gerbils (e.g., Daly and Daly 1973). At the end of the postdoc and looking for a change, Martin and Sandra bought an old Victorian house in Nova Scotia and planned to live off the land. They planted vegetables and bought a goat to make their own yogurt. As the winter approached, however, Martin became intellectually bored, having read all the books in the bookmobile parked nearby. Sandra also had a change

of heart about their lifestyle. Their back-to-the-land experiment and marriage ended.

Martin Daly returned to the University of Toronto in late 1974 where he worked as a volunteer postdoc with his previous supervisor, J. Hogan, and began applying for academic jobs. After first meeting Margo Wilson on campus when submitting an ethics application, they met again in the summer of 1975 at the meeting of the Animal Behavior Society in North Carolina (Belluz 2009; Daly 2012). At that time, the conference was a common meeting ground for those interested in both nonhuman and human behavior. The pair's interests coincided, and according to Martin, at the end of the meeting, "I followed her home back to Toronto, and I wouldn't leave." (Belluz 2009). It was the beginning of a long and productive personal and academic partnership.

Daly and Wilson: A First Book with Longevity

His job search successful, Martin Daly was Lecturer and Assistant Professor in Psychology at the University of California, Riverside from 1975 to 1978. Margo accompanied him and was Visiting Assistant Professor at the University of Southern California (1977) and Visiting Scholar, University of California, Riverside (1977–1978). During their first year, they attended a seminar where participants discussed each chapter of E. O. Wilson's groundbreaking new book *Sociobiology: The New Synthesis* (1975). In the oversized volume, Wilson assembled the foundations of a new discipline encompassing an evolutionary functional analysis of social behavior. Convinced by the approach and wishing to extend its coverage of human behavior, Daly and Wilson decided to write a book to marry proximate and ultimate approaches in the behavioral sciences (Daly and Wilson 1983; Krupp and Barclay 2010). They began working on their first book *Sex, Evolution, and Behavior* (1978), and by 1976, it was largely complete. After Martin attended the conference of the American Anthropological Association in Washington, D.C., they added two final chapters

devoted to human evolution and psychology. The book brought together basic evolutionary concepts and theory, including natural selection, fitness, evolution of sex, sex allocation, parent-offspring conflict, sexual selection, and life history strategies, with numerous applications to the behavior and physiology of both nonhumans and *Homo sapiens*. Filling a new niche in a highly readable way, the volume was immediately taken up by students, academics, and the lay public, with a second edition following in 1983. The clarity and accuracy, with which the chapters covered the theoretical foundations while peppered with real-world examples, resulted in it serving as a textbook for many years, even as recently as a few years ago. Due to the interest and rapid research progress largely inspired by Daly and Wilson's first book and approach, ironically the only chapters that became quickly outdated were the final ones devoted to human evolution and psychology.

In 1978, the pair returned to Canada with Martin taking up the position of Associate Professor of Psychology at McMaster, where he taught some of the earliest classes on sociobiology and human evolution and behavior. Margo became a Research Associate, as antiquated regulations against hiring faculty members' spouses prohibited her from a formal university position for decades (Krupp and Barclay 2010). Every November the couple packed up their station wagon in Hamilton and traveled south. While at Riverside, they had begun conducting field research on the behavior and ecology of Merriam's kangaroo rats at the Boyd Deep Canyon Research Center near Palm Desert, California. Although a research station in the desert sounds completely idyllic, along with their students and postdoc, Daly and Wilson put in long hours tracking kangaroo rats at night. At times, when nighttime temperatures plummeted, they would huddle up under newspapers to keep warm. The fieldwork continued for about three decades and resulted in numerous contributions concerning the ecology and behavior of the nocturnal rodents, including the function of scatter hoarding in reducing major cache loss and modulation of differential predation risk according to

moon phase (e.g., Daly et al. 1992). Each year throughout the 1980s on their way to and from the field station, Randy Thornhill recollects the couple visiting his home in New Mexico, which was also his study site for a project on sexual selection in red junglefowl. True to form, Margo and Martin enjoyed watching and hypothesizing about the junglefowl's behavior. Always up for a good meal, they also joined the Thornhills in feasting on the birds during their many stopovers.

In the late 1970s, during their stay in California or return to Canada, Margo began thinking about undertaking research on *Homo sapiens*. After some time she was struck with the idea that the incidence of human homicide may serve as a porthole through which evolved human passions and biases could be revealed. She readily convinced Martin they should conduct epidemiological analyses of patterns of risk for violence in different kinds of human relationships, such as marital, parent-offspring, and male-male. Thus began a 30-year program of research that would be the focus of much of their later human empirical studies. Soon after, Margo and Martin visited the Detroit police station to discuss researching their homicide records, launching a long-term cooperative enterprise including the police and several other researchers in fields related to jurisprudence and law enforcement (Daly and Wilson 1988; Daly 2016).

Patterns of Homicide and the Birth of a Society

In 1978, Daly and Wilson were invited to an informal conference on human behavior and evolution organized by Richard Alexander and Donald Tinkle at the University of Michigan in Ann Arbor. The meeting also included William Irons, Napoleon Chagnon, and their students from Northwestern University. Over the next 10 years, Wilson, Daly, and their students would regularly drive from McMaster to Ann Arbor for the continuing meetings. Between 1986 and 1995, the *Evolution and Human Behavior Program* was supported by the University of Michigan. In addition to the main organizers, Richard Alexander and Bobbi Low, others affiliated with the program

or attending meetings who would make their own mark on the discipline included David Buss, Barbara Smuts, Laura Betzig, Paul Turke, Monique Borgerhoff-Mulder, Beverly Strassmann, Randolph Nesse, Richard Wrangham, Eugene Burnstein, Elizabeth Hill, Mark Flinn, Warren Holmes, George Williams, William Hamilton, Robert Axelrod, Jack Beckstrom, Mildred Dickemann, John Hartung, and Randy and Nancy Thornhill. Initially the meetings were sufficiently small and informal that a reception was usually held at someone's home, including Richard Alexander's farm.

Cross-border exchanges continued, and in 1984–1985, Wilson and Daly were Visiting Scholars in Biological Anthropology at Harvard University. There they took part in the “Simian Seminars” held by the prominent Harvard primatologist and anthropologist, Irvén DeVore, at his Cambridge home (Hrdy 2005) and attended less formal meetings at North House (Daly and Wilson 1988). During this time Martin and Margo first met Leda Cosmides and John Tooby, who (along with others like Don Symons) would champion a focus on evolved mental mechanisms rather than behavior per se (e.g., Tooby and Cosmides 1989), and David Buss, whose seminal work on human mate selection would establish a new and popular subfield. A special project “Foundations of Evolutionary Psychology” proposed by Buss (Buss 2008) resulted in the four working together in 1989–1990 at the Center for Advanced Study in the Behavioral Sciences at Stanford University where they cemented their mutual and individual approaches. By this time Wilson and Daly had also given numerous presentations to colleagues and students at developing centers of interest in Canada, such as those led by Charles Crawford and Dennis Krebs at Simon Fraser University and Irwin Silverman at York University.

Throughout the 1980s Margo and Martin pursued their epidemiological investigations of human violence. An initial foray with colleague Suzanne Weghorst produced the striking and novel finding that stepchildren were about 100 times more likely to be lethally abused than biological children (Wilson et al. 1980). This they attributed to an evolved bias in parental solicitude

favoring one's own biological children, now widely known as “discriminative parental solicitude” (Daly and Wilson 1980). Predicting that male-male competition over mates would also impact violence, they found that male sexual jealousy and suspicions of infidelity were predominant motives in lethal assaults of wives (Daly et al. 1982). Moreover, they suggested that the heightened levels of violence displayed by young men, or “the young male syndrome,” may reflect sexually selected competitive risk-taking (Wilson and Daly 1985). In 1988, Daly and Wilson published their second book, *Homicide*, a landmark describing many of their previous studies and serving as a model for future research programs. The book began with the theoretical underpinnings of the evolution of motivations toward lethal violence. In subsequent chapters predictions regarding the expected patterns of interpersonal conflict, violence, and homicide were tested citing their earlier findings, other modern samples, and diverse datasets, including those based on hunter-gatherers, indigenous peoples on the Indian subcontinent, a thirteenth-century English sample, and cases of infanticide in the Human Relations and Area files. Interestingly, the book also considered the codevelopment of legal systems constructed to contend with violence. Their investigations had piqued Margo's interest in law, and in 1987, she became the first graduate of the Masters of Studies in Law program at the University of Toronto (Belluz 2009; Daly 2012; Gaulin and Fessler 2010). Although she had not known her maternal grandfather, in later life Margo had come to share his calling, receiving a law degree about 90 years after he was called to the bar.

In 1988, two larger formal conferences, the *Evolution and Human Behavior Conference* and *Evolutionary Psychology and Psychiatry Conference* were held at the University of Michigan. At the latter, Wilson and Daly attended a meeting to discuss future conferences and creation of a formal society. As a result the *Human Behavior and Evolution Society* (HBES) was founded October 29, 1988 with William Hamilton elected first president (Low and Nesse 1989) and the inaugural meeting held at Northwestern University in

1989. A primary instigator, Randy Nesse, remembers that along with others, Martin and Margo were initially skeptical about the success of the new society. However, they quickly became two of its greatest adherents, cheerfully greeting other participants at the meetings each year. Along with Daly and Wilson, several of the early attendees would be recognized as founding members of the society and the new discipline of evolutionary psychology. Thus with the 1980s coming to a close, a new offshoot of E. O. Wilson's *Sociobiology*, focusing more specifically on the functional evolution of human psychological mechanisms and behavior with its own society, had firmly taken root.

Maturation and Internationalization of the New Discipline

During the decades bookending the turn of the millennium, Wilson and Daly played important roles in guiding the further progress and internationalization of evolutionary psychology. Martin Daly was president of the Human Behavior and Evolution Society in 1991–1993 and executive council member from 1989 to 1995. Margo Wilson served as president from 1997 to 1999 and as executive board member from 1992 to 1999. During that time the society's membership and conference attendance rose steeply. In 1996, *Evolution and Human Behavior* (formerly *Ethology and Sociobiology*) became the flagship journal of HBES, and Daly and Wilson became coeditors in chief for the next 10 years. Through their expert stewardship, rigorous standards, and constructive criticism, the journal became a highly cited repository of cutting edge research and theory. For some time it was the primary journal where articles taking a functional approach to human behavior and psychology could be reviewed without fear of disqualification due to antievolutionary biases. Advancement of the journal at this juncture was critical to the expansion and progress of the new discipline.

In concert with the success of the international society came further involvement with researchers in other countries. In 1993, Margo

and Martin spent time with colleagues at Rockefeller Foundation Center in Bellagio, Italy, were Visiting Professors at the University of New Mexico (1996–1997), and fellows at the Wissenschaftskolleg zu Berlin in 2002. In addition to presentations in Canada and the USA, Daly and Wilson gave numerous invited lectures in diverse countries, including Brazil, the Netherlands, Turkey, Japan, Germany, Australia, Sweden, Chile, and the UK. The pair actively promoted international and interdisciplinary research and supported colleagues in other nations, with Margo assisting them in successful grant applications (Daly 2012; Krupp and Barclay 2010). In addition, Martin served terms on the executive committees of the International Society for Behavioural Ecology and Animal Behavior Society, and both sat on editorial boards for other respected journals. With their international reputations firmly established, in 1998, Margo Wilson and Martin Daly were honored in their home country when they were named fellows of the Royal Society of Canada.

With funding from several bodies, including the prestigious Harry Frank Guggenheim Foundation and armed with theoretically derived predictions, Daly and Wilson meticulously raked extant homicide and new datasets, turning up a chain of novel findings. Margo was particularly interested in identifying the determinants of spousal homicide and violence against women and found, for example, that the risk of uxoricide (killing one's wife) was heightened following a separation, and among younger wives and those in common-law relationships (Wilson et al. 1995). She argued that male sexual jealousy and possessiveness or "male sexual proprietariness" was a primary motivation of spousal violence (Wilson and Daly 1996). Building upon their earlier proposition that elevated male aggression is related to risk-taking, Margo reasoned that risk acceptance or future discounting and homicide rates may be heightened when life expectancy is low. Sure enough, a study of Chicago neighborhoods showed local life expectancy was a major predictor of homicide rate and future discounting, as measured by age of first reproduction (Wilson and Daly 1997). Moreover, income inequality was a positive predictor

of homicide rates. A later related experimental study indicated that men shown photographs of attractive women to induce a “present oriented mindset” discounted the future more than those shown less attractive photographs of women (Wilson and Daly 2003). Martin followed up on the findings of increased risk of violence toward stepchildren, dubbed the *Cinderella effect*, finding that women with children from a previous partner were at increased risk of uxoricide (Daly et al. 1997). In 1998, he and Margo published their third book, *The Truth about Cinderella*, a volume in the popular series *Darwinism Today*, covering much of their work on discriminative parental solicitude.

After holding adjunct positions at McMaster University for a decade, Margo Wilson was formally appointed Professor of Psychology in 1998. In their classes and busy research lab at McMaster, Margo and Martin encouraged the academic careers of their students. Genuinely interested in their students’ lives, the pair held get-togethers at their home where tasty dishes always complemented the social menu. Never assuming credit for students’ original work, they published with them as colleagues on diverse topics, such as variability in sociosexuality, birth order and familial sentiment, differential cache pilferage, and evolution of the family. In 2003, Margo was diagnosed with non-Hodgkin’s lymphoma, but nevertheless continued with her active life, teaching, and research. Fulfilling a long-held wish, during the summer of 2008, Martin and Margo took a cruise to the Galapagos Islands, a location fomenting Darwin’s greatest insight (Fig. 1). There they took in the scenery, peered at the peculiar island inhabitants, and added Darwin’s finches to their bird life lists accumulated over many years as avid birdwatchers.

In 2009, Daly and Wilson were honored with a Lifetime Achievement Award by the HBES at the first meeting the couple would miss, due to Margo’s failing health. The society and discipline lost a much-admired pioneer when Margo died in Hamilton on September 24, 2009. In 2010, the first Margo Wilson Award of the HBES, honoring her contributions to the society and discipline, was presented at the annual meeting. Martin retired from McMaster in 2011, but took up a

Martin Daly and Margo Wilson (Founders of Evolutionary Psychology), Fig. 1 Margo Wilson and Martin Daly in the Galapagos Islands, 2008 (Courtesy of M. Daly)

Research Professorship at the University of Missouri the following year, continuing his research alongside his present wife, Gretchen Perry. While in Missouri, he wrote his recent book *Killing the Competition: Economic Inequality and Homicide* (2016). In an engaging, personal style, Martin convincingly lays out the case that economic disparity within populations is not just positively correlated with homicide rates across populations but is causal. His argument builds upon he and Margo’s 1997 findings, as well as those showing reduced homicide rates and income inequity in Canada versus the USA (Daly et al. 2001). Also highly relevant is their finding that the most common form of lethal violence, male-male violence, is the most variable across populations (Daly and Wilson 1988) and perhaps the most amenable to economic intervention. As in *Homicide* (1988), his case is made through the presentation of an array of empirical findings, coupled with established theory and undeniable logic. In the process, Martin dissects and debunks myths including that it is absolute level of resources, not inequity, that drives violence, and that financial policies to reduce inequities inevitably decrease productivity and economic growth.

Conclusion

Together Margo Wilson and Martin Daly introduced a wide audience to evolutionary thinking in

the behavioral sciences through their four books and over 250 theoretical, review, and empirical papers. Their work appears in more than 70 different journals, signaling its broad appeal across disciplines, including criminology, biology, anthropology, law, sociology, and economics. Additionally, they have given at least 200 invited talks or presentations and nurtured the careers of over 20 graduate students and postdocs. Spanning several decades and continents, Martin Daly and Margo Wilson's scientific rigor and zeal galvanized others, helping to carve a clear pathway for the emerging field of evolutionary psychology. Their contributions to the *HBES* and *Evolution and Human Behavior* remain ever inscribed reminders of the extensive and enduring stretch of their influence. Although Darwinism had a slow start in Canada, Daly and Wilson played crucial roles at the frontier of its most modern application to psychology and behavior.

Martin Muller

Giovanni Randazzo
Department of Psychology, Oakland University,
Rochester, MI, USA

Definition

Martin Muller, Associate Professor in the Department of Anthropology at University of New Mexico, Co-Director of Kibale Chimpanzee Project and Kibale National Park.

Introduction

Martin Muller is an associate professor and anthropologist at the University of New Mexico. He studies behavioral and reproductive ecology, endocrinology, and evolution in primates including humans. Dr. Muller is the co-director of the Kibale Chimpanzee Project and Kibale National Park. He earned both his Bachelors and Doctorate in Anthropology at the University of Southern California. In recent work, Dr. Muller has co-authored the book *Sexual Coercion in Primates: An Evolutionary Perspective on Male Aggression Against Females* with Dr. Richard Wrangham and has published research on chimpanzees and comparative work on human reproductive behavior.

Kasiisi Project and Kibale Chimpanzee Project

The Kasiisi Project, located in Uganda, was founded in 1997 in order to aid in educating in tangent with the Kibale National Park. The Kasiisi Project serves as a link between locals and the Kibale Chimpanzee Project (Kasiisi Project 2017). The Kibale Chimpanzee Project, founded to study the behavior, ecology, and physiology of wild chimpanzees in 1987 (Kibale Chimpanzee Project 2017), has been dedicated to the survival, welfare, and understanding of chimpanzees (Kibale Chimpanzees 2013). Some recent research by Dr. Muller done with the Kibale Chimpanzee Project involves social customs, reproduction, hormones, and disease in chimpanzees (The Kibale Chimpanzee Project 2017).

Recent Research

Recent comparative work on humans done by Thompson and Muller (2016) has examined human reproductive behavior in comparison to other primates. In this entry, they examine fluctuations of hormones in fertile versus non-fertile periods under such hypotheses as the dual-mating hypothesis. In the discussion, they come to the conclusion that the dual-mating hypothesis is not a suitable explanation for the extended sexuality found in humans when comparing to other primates. They further conclude that additional research is needed on hormone-mediated shifts in female sexual psychology (Thompson and Muller 2016).

In some recent publications of Dr. Muller's work with chimpanzees, he has examined social constructs within chimpanzee groups including grooming behaviors and learning, foraging, and hunting calls. Chimpanzees' have unique grooming styles per group in and out; how these styles developed were unknown. Wrangham et al. found that individuals keep their mother's style and are not influenced by other chimpanzees, impacting community traditions for generations (Wrangham, et al. 2016). Foraging in chimpanzees is primarily done by females; however their

ability to forage is affected by their group, particularly how many males are in the group and if they have children. In a recent article, Thompson et al. determine that having many males in a group has long-term costs associated with reproduction via negative affect on C-peptide levels and foraging capabilities (Thompson et al. 2014). Hunting initiative of chimpanzees has also been examined, finding that groups of male chimpanzees often have constant initiators that spur on the group to hunt, including non-common hunting participants within the group. After the removal or death of the common initiators, fewer hunts are enacted (Gilby et al. 2015).

Conclusion

Dr. Martin Muller studies a variety of subjects in relation to primates. He is the co-director of the Kibale Chimpanzee Project and Kibale National Park. His recent work has compared human reproductive behavior to other primates, and he has examined behaviors in chimpanzees such as grooming behaviors and learning, foraging, hunting calls, and more alongside others in his field.

Maryanne Fisher is a psychologist best known for her work on women's intrasexual competition and applying an evolutionary framework to popular culture.

Introduction

Dr. Maryanne Fisher is a full professor in the Department of Psychology at Saint Mary's University in Halifax, Canada. The majority of her research has focused on women's intrasexual

competition for access to, and retention of, mates. Her first noteworthy contribution to evolutionary psychology was an empirical examination of women's derogation of other women according to ovulatory cycle phase (Fisher 2004). More recently, she has turned her interest towards maternal competition in women. Other significant contributions include examinations of literature and popular culture, including Harlequin romance novels, co-editing *Evolution's Empress: Darwinian Perspectives on the Nature of Women* (2013), and editing *The Oxford Handbook of Women and Competition* (2017).

Women's Intrasexual Competition

In 2004, Fisher published the first empirical study of women's intrasexual competition for mates. She proposed that the decrease in ratings of female facial attractiveness during ovulatory cycle phases marked by high estrogen as compared to low estrogen indicated derogation of potential mating competitors. A similar finding was not obtained for male faces, showing this decrease was potentially related to competition for finding a good mate, rather than simply a decrease in global evaluations of facial attractiveness. She then went on to demonstrate that romantic relationship status, self-monitoring, and sociosexuality did not lead to differences in evaluations of attractiveness, and those who were single and actively seeking a mate did not differ from those single and not seeking a mate (Fisher et al. 2008). These findings highlight that intrasexual competition for mates may not be influenced by romantic relationship status or one's engagement in actively seeking a mate.

She has also examined the strategies that one may use in intrasexual mating competition. Her research shows that there are four primary strategies that people use. Self-promotion is when one attempts to make her/himself seem superior to rivals, such as by dressing nicely or drawing attention to positive personality traits. Competitor derogation instead is when one attempts to devalue a potential rival, relative to oneself, such as by making negative statements about a rival's

sexual history. Self-promotion and competitor derogation had been documented prior to Fisher's research. However, she found the additional strategies of competitor manipulation and mate manipulation. Competitor manipulation is reducing the actual need to compete by manipulating one's rivals, such as telling a rival that a targeted mate has a history of sexual diseases. Mate manipulation is when one attempts to direct the attention of a mate toward oneself and away from a potential rival. She found that self-promotion was the most used strategy, followed by mate manipulation, and that competitor derogation and competitor manipulation were used to the same extent (Fisher and Cox 2010). She has outlined these strategies further in a recent theoretical paper (Fisher 2015) and reviews the area in Fisher (2013).

Until recently, she primarily investigated the ways that young heterosexual women competed for access to, and retention of, mates. However, her focus has shifted from not only examining mating competition but also to study competition between mothers. Women, ultimately, must act in ways to improve their reproductive success, whether it takes the form of mating competition or mother's competing for access to resources that impinge upon their children's health, survival, and their subsequent reproduction. This line of inquiry has, to date, remained primarily theoretical (e.g., Fisher and Moule 2013; Fisher et al. *in press*).

Evolutionary Psychology and Popular Culture

Starting in 2003, Fisher (along with collaborators), began to apply the lens of Darwinian literary criticism towards a variety of media. The premise of this framework is that one may explore media to understand human's evolved motives, cognitions, emotions, and behaviors. In 2012, along with Dr. Catherine Salmon, she co-edited the June 2012 issue of the *Review of General Psychology* on the intersection of popular culture and evolutionary psychology. She has investigated men's and women's mating strategies in Victorian

romance fiction (e.g., Kruger et al. 2003), as well as in contemporary romance novels (Cox and Fisher 2009), television sitcoms (Fisher 2012), graffiti (Fisher and Radtke 2014), and song lyrics (Fisher and Candea 2012). She has also explored the topics of Western paintings, as well as the topics of what women paint specifically, proposing that these topics must at least partly reflect evolved human nature (Fisher and Meredith 2012).

Evolution's Empress and the Oxford Handbook

Fisher co-edited, with Dr. Rosemarie Sokol-Chang and Dr. Justin Garcia, *Evolution's Empress: Darwinian Perspectives on the Nature of Women* in 2013. This volume was inspired by the formation of the Feminist Evolutionary Psychology Society, which showed the need to formally address how women have been active agents during human evolution. The book contains 22 chapters, spanning a range of topics such as health and reproduction, competition and cooperation, parenting, and mating and communication. An offshoot of this book led to working with Sokol-Chang to edit the December 2013 issue of the *Journal of Social, Evolutionary and Cultural Psychology* on the intersection of feminism and evolutionary psychology.

More recently, Fisher has edited *The Oxford Handbook of Women and Competition* (2017). Many but not all of the chapters in this book incorporate an evolutionary perspective. The book contains 39 chapters that range in their focus; topics include social status and aggression, gossip, mating relationships, endocrinology, health and aging, family, physical appearance, virtual considerations, workplace issues, and sport.

Conclusion

Maryanne Fisher is best known for developing the area of women's intrasexual competition for mates and has begun to examine maternal competition in women. Other significant contributions

include examinations of literature and popular culture, co-editing *Evolution's Empress: Darwinian Perspectives on the Nature of Women* (2013), and editing *The Oxford Handbook of Women and Competition* (2017). Collectively, her work has helped to challenge prior assumptions regarding women's passivity in humans' evolutionary history.

Masculinity and Femininity

Barnaby J. W. Dixon
School of Psychology, The University of
Queensland, Brisbane, QLD, Australia

Synonyms

[Femaleness](#); [Gender](#); [Maleness](#)

Definition

Masculinity and femininity refer to an individual's gender in terms of maleness and femaleness, respectively. Gender roles are those socially ascribed normative behaviors with respect to a given gender. Biological sex refers to an individual's reproductive organs as being male or female.

Introduction

Issues surrounding sex and gender roles as they relate to sexuality are among the most divisive across scholarly disciplines. If one adheres strictly to the definitions, sex is biological and defines individuals based on their reproductive anatomy into male and female, while gender refers to one's maleness (masculinity) and femaleness (femininity). Gender roles are those societally constructed normative behaviors ascribed to a given gender that, in turn, are attached to a particular biological sex. For those with backgrounds in social theory, biology may have little to do with how cultural norms color the blank canvas that becomes adult gender identities and roles. An alternative view is that gender bears the stamp of past selective pressures and has been shaped by natural selection. One of the most sexually dimorphic aspects of human behavior and biology concerns reproduction and parental roles. This entry explores the relationships between sexual dimorphisms in morphology and gender-typical parental roles.

Sexual Reproduction and Social Roles in Humans

Parental investment theory proposes that sex differences in reproductive investment should lead to differences in mate preferences (Trivers 1972). Given that females invest more biological resources in offspring than males, they form a scarcer resource, potentially driving male-male competition to attract and retain mates, a paradigm that has become known as the “males compete and females choose” paradigm (MCFC). However, humans have also evolved a cooperative mating system, wherein fathers and alloparents contribute to the survival of children (Sear 2016). Thus, how sexual selection has shaped the evolution of reproductive anatomy, secondary sexual traits, and gender differences in parental roles should be understood as occurring within complex social and mating systems (West-Eberhardt 2014).

Foundational theories in evolutionary psychology suggested that mate preferences were shaped in the early phases of human ancestral evolution to

attend to morphology that provides information relating to biological quality, including fertility, health, and parental skills (Grammer et al. 2003). In a seminal article, Buss (1989) demonstrated across 37 cultures that men stated stronger preferences than women for youth and physical attractiveness in a mate, whereas women stated stronger preferences than men for older partners with greater earning potential. Research among the Hadza hunter-gatherers of Tanzania reported that the most important traits nominated in a spouse were character, foraging ability, and physical attractiveness (Marlowe 2004). The only sex differences in mate preferences were a higher importance placed by men than women on fertility and women's greater emphasis on intelligence than men (Marlowe 2004). These findings provide some support for parental investment theory in shaping the evolution of mate preferences.

It follows logically that if preferences have evolved to attend to characteristics that are associated with health, fecundability and parental qualities then meaningful correlations could exist between sex-typical secondary sexual traits and gender-typical parenting behaviors in women and men. The following sections will discuss the extent to which any such relationship exists and the implications this has for understanding the evolution of mate preferences.

Femininity in Women: Morphology and Maternal Tendencies

Sex-typical or "feminine" traits emerge in women under the actions of estrogens during pubertal development. These include facial traits such as a round overall shape, wide eyes, and full lips and bodily traits such as permanent stores of fat around the hips, buttocks, thighs, and breasts (Grammer et al. 2003).

Given the physiological investments women make in birthing and raising offspring (Jasienska 2009), if sexual selection has shaped men's preferences for femininity as indicators of fecundability and maternal investment, then information about maternal investment capabilities may be reliably conveyed in secondary sexual traits. Facial femininity in women is indeed positively associated with fecundability as measured

in reproductive hormones and women's desire to invest maternally (Law Smith et al. 2012). In contrast, testosterone levels and height were negatively associated with desired number of children and ideal age at first reproduction (reviewed in Law Smith et al. 2012). Higher self-reported maternal tendencies also predict women's motivational responses to infants (Hahn et al. 2015). Men judge more feminine-looking women to be warmer, trustworthy, cooperative, and more sexually attractive than more masculine-looking women (Grammer et al. 2003).

The significant energetic investment in gestation and lactation suggests a healthy distribution of body fat, and fully developed breast morphology might also be associated with maternal tendencies. A low waist-to-hip ratio (WHR), wherein the waist is narrower relative to greater fat reserves in the buttocks and thighs, in concert with a healthy body mass index, is associated with various facets which are reproductive maturity and fecundability in women (Singh and Singh 2011). Thus, the onset of menarche in adolescence and the ability to maintain regular menstrual and ovulatory cycles during adulthood are associated with low WHRs, as is fertility, and healthy offspring birthweight (Singh and Singh 2011).

Fat around the mammary glands provides energy for lactation (Anderson 1983). Although it was once thought that breasts function as storage organs for milk and in rare cases deficiencies in glandular development are associated with reduced success in initiating breastfeeding, the overall size of non-lactating breasts does not indicate actual lactation ability or milk storage capabilities (reviewed in Dixon et al. 2015). Others proposed that permanently enlarged breasts evolved to allow for breastfeeding during bipedal movement and that resting an infant against the breasts is psychologically comforting (reviewed in Dixon et al. 2015). Maternal-infant bonding via breastfeeding is likely an ancient feature of human maternal-infant bonding, and there is some evidence that breastfeeding enhances infant immune response (Duijts et al. 2009) and lowers maternal stress via prolactin and oxytocin release, which may further facilitate maternal-infant bonding (Uauy and de Andraca 1995).

While men's preferences for breast size differ both within and between cultures (reviewed in Dixon et al. 2015), breast size emerges as a strong predictor of female physical attractiveness in multivariate evolutionary studies (Brooks et al. 2015). Likewise, male preferences for specific values of WHR vary cross-culturally (reviewed in Brooks et al. 2015), likely due to greater variation explained by BMI in attractiveness judgments (Swami and Tovée 2005). However, body fat distribution contributes significantly to men's judgments of female physical attractiveness (Brooks et al. 2015). There is also some evidence that men and women judge larger breasts as more sexually mature, as reproductively capable, and as providing greater maternal nurturance (defined as breastfeeding and caring for infants; Dixon et al. 2015). However, empirical data demonstrating that women's body size, shape, or breast morphology are meaningfully associated with self-perceived or actual maternal investment in offspring, infant bonding, or offspring survivability appear to be lacking from the literature. Moreover, how sexual dimorphisms in women's morphology underpin maternal investment in small-scale societies will be critical to ascertain in future research. Thus, although some sex-specific aspects of female body composition are associated with biological aspects of maternal capabilities, for the present, there is a lack of empirical data linking such morphology to behavioral aspects of maternal investment in offspring and offspring fitness.

Masculinity in Men: Morphology and the Masculinity Paradox

Sex-typical male traits develop under the actions of androgens during pubertal development. These include craniofacial masculinity (i.e., enlarged brow ridge, thicker jaw, small eyes, and more robust midface), facial and body hair, vocal pitch, height, and muscularity (Grammer et al. 2003). Boys typically reach sexual maturity later than girls, which suggests that secondary sexual traits manifest when competition to attract viable mates is augmented. According to life history theory, males who attain sexual maturity more rapidly will display earlier development of

masculine secondary sexual characters as they influence mating effort (Muehlenbein and Bribiescas 2005). Earlier recall of pubertal development is associated with greater body size, upper body strength, and aspects of masculine facial shape (Doll et al. 2016), and more dominant-looking teenage boys report greater numbers of sexual partners than their more submissive-looking counterparts (Mazur et al. 1994). In adulthood, men with more masculine faces and deeper voices established higher positions in male dominance-based hierarchies and attained greater mating success (reviewed in Puts 2016).

While masculine secondary sexual traits require androgens for their expression, the allocation of resources toward traits associated with mating effort may come at the expense of some aspects of somatic health (Muehlenbein and Bribiescas 2005) and result in reduced paternal investment (Gettler 2016). Indeed, men with more masculine faces and bodies report engaging in more short-term than long-term relationships, and women accurately judge sexual infidelity from masculinity in static photographic stimuli (reviewed in Dixon et al. 2016). Thus, unlike in women where estrogen-dependent characteristics are to some extent associated with maternal tendencies, in men androgens underpin sexually selected traits that positively predict men's mating success but may be associated with reduced paternal investment.

This suggests there are costs to women in selecting masculine partners. However, preferences for attractive traits have evolved as they confer indirect (i.e., genetic) benefits to offspring or direct benefits such as resources, increased survivability, or enhanced fertility (Kokko et al. 2003). Masculine craniofacial traits are judged as less warm, caring, having less interest in long-term relationships, and providing lower paternal investment (reviewed in Dixon et al. 2016). Thus, reduced phenotypic masculinity may be preferred in a long-term mate, as such men are perceived as more socially amenable, cooperative, and paternally investing as long-term partners (reviewed in Dixon et al. 2016). However, mating strategy theories suggest that the costs associated with selecting masculine

mates are bypassed when women pursue more short-term mating strategies (reviewed in Dixon et al. 2016). Indeed, studies have reported augmented preferences for masculine faces, body shape, vocal pitch, and scents among women when judging short-term than long-term attractiveness (reviewed in Dixon et al. 2016). These preferences may also be greater at the follicular, more fertile, phase of the menstrual cycle when any benefits to offspring fitness gained by selecting a masculine mate are more likely to be realized (Gildersleeve et al. 2014). Although these strategic trade-off models have been popular in the past 15 years of research, a recent large study among identical and nonidentical twins reported that 38 % of the variance in women's facial masculinity preferences was due to genetic variation, while individual differences in sociosexuality, fertility, and pathogen disgust are combined to explain less than 1 % of the variance (Zietsch et al. 2015). These findings call into question the importance of contextual factors in maintaining variation in preferences for masculinity in short-term mates.

Given that androgen-dependent masculine traits are associated with reduced paternal qualities but some aspects of biological quality, facultative trade-offs may underpin the strength of women's masculinity preferences cross-culturally (DeBruine et al. 2010). In a cross-cultural study of women's facial masculinity, preferences were found to be strongest in countries and where national health was lowest (DeBruine et al. 2010). Alternatively, the value of an intra-sexually formidable mate may underpin women's masculinity preferences when resources are scarcer. A reanalysis of the data from DeBruine et al. (2010) reported that national income inequality was a stronger predictor of women's preferences than national health (Brooks et al. 2011). These studies highlight a role of ecological and economic factors in shaping preferences for masculine facial morphology. However, whether variation in preferences reflects any trade-offs in preferences for genetic quality or direct benefits and how either of these forms of sexual selection relate to paternal investment qualities in humans remain to be determined.

It is important to note that aside from the aforementioned cross-cultural analyses (DeBruine et al. 2010; Brooks et al. 2011), the majority of the conclusions in studies of women's preferences for men's facial masculinity are derived from data collected among predominantly WEIRD (Western, Educated, Industrialized, Rich, and Democratic) populations (reviewed in Scott et al. 2014), which represent only a fraction of the current cultural and ecological variation across human societies (Heinrich et al. 2010). Further, they may not reflect the kinds of environments in which preferences are argued to have evolved (Grammer et al. 2003) and instead could represent mate preferences formed within more modern and ecologically novel circumstances. Indeed, a recent cross-cultural study of preferences for sexual dimorphism in facial morphology that included data from several small-scale societies reported preferences for sex-typical facial traits were stronger in cultures with higher human development indexes (Scott et al. 2014). In these settings, people are more regularly exposed to a greater number of anonymous people compared to people living in small-scale societies, which may drive greater sensitivity to small variation in craniofacial masculinity (Scott et al. 2014). Another possibility is that within small-scale subsistence societies where paternal and maternal gender roles are more rigidly defined (Marlowe 2000), asking people to complete mate preference tests that included questions relating to their ecological or social context, such as how much the stimulus or target might invest parentally, may be more effective in exposing any trade-offs in mate preferences. What is clear from these studies is that further comparative cross-cultural analyses among small-scale and multilevel societies would be valuable.

Conclusion

The goal of this article was to highlight that some quite basic questions regarding the relationship between gender roles in parenting qualities and sexual dimorphisms in morphology that have putatively evolved via sexual selection remain

unanswered. A challenge for the next generation of students in evolutionary psychology and human behavioral ecology may be to characterize how variation in culture, ecology, and genetics combine to maintain variation in parental gender roles and mate preferences.

London, London, UK

Synonyms

Concealing imitation; Procryptic resemblance;
Special resemblance

Definition

When an organism appears to mimic an inanimate object, ostensibly, so that predators or prey misclassify it as unimportant.

Introduction

It is a relatively common strategy among plants and animals to mimic inanimate objects (“models”), such as twigs, leaves, pebbles, and bird droppings (Skelhorn et al. 2010a). Among insects, at least 50 of the 950 species of British

macrolepidoptera resemble inanimate objects. For example, caterpillars of the peppered moth, *Biston betularia*, look like the twigs of birch and willow trees on which they rest; most of the 2500 species of stick and leaf insects (Phasmatoidea), as well as many mantises (Mantodea), also resemble leaves and twigs (Skelhorn et al. 2010b). In terrestrial vertebrates, birds from the genus *Nyctibius*, with bark-colored plumage, are suggested to masquerade as tree stumps by sitting motionless during the day (Caro 2014). Tree-living colubrids, which have long thin bodies, are thought to resemble vines both in appearance and behavior (Caro 2014). In aquatic vertebrates, the nocturnal Amazonian catfish, *Tetranematichthys quadrifilis*, resembles a waterlogged leaf, and the leafy sea dragon, *Phyllopteryx eques*, closely resembles seaweed (Cott 1940). In plants, the variegated leaves of *Silybum marianum* are believed to masquerade as leaves that have been damaged by tunneling insects (Lev-Yadun 2014). Stone mimicry is very common in at least four families of plants, *Mesembryanthemaceae*, *Crassulaceae*, *Euphorbiaceae*, and *Liliaceae*, from arid regions of southern and northeastern Africa and also North America (Lev-Yadun 2014).

This resemblance of inanimate objects has been referred to by a number of terms including “special resemblance,” “procryptic resemblance,” “plant part mimicry,” and “concealing imitation,” but it is now widely known as “masquerade.”

How Does Masquerade Work?

In 2010, Skelhorn et al. showed that domestic chicks that had prior experience of twigs were slower to attack twig resembling caterpillars compared to chicks that had no experience or experience with twigs that no longer resembled the caterpillars because they had been bound in purple cotton twine. This experiment provided the first evidence that experienced birds generalize their learned indifference toward twigs to twig-resembling caterpillars and misclassify caterpillars as twigs. This study also showed that caterpillars benefitted from masquerade even

when they did not match their background, which was the first evidence that masquerade operates in the absence of background matching (crypsis).

Skelhorn et al. (2011) also showed that masquerade is less effective as an antipredatory defense when the density of masqueraders is increased relative to their models. This is because predators are less motivated to search for masquerading caterpillars if their recent experience suggests a high, rather than low, local density of unrewarding twigs and because a greater number of models make it more difficult for predators to detect masquerading prey.

How Does Masquerade Differ from Crypsis and Batesian Mimicry?

Masquerade is distinct from crypsis. Cryptic animals are difficult to detect, whereas masquerading animals are detected but mistaken for inanimate objects (Skelhorn et al. 2010a).

Similar to masquerade, predators mistake palatable Batesian mimics for the defended species (“models”) that they resemble. However, in Batesian mimicry, an increase in the number of mimics causes predators to attack the model more frequently. Therefore, Batesian mimics influence the population and evolutionary dynamics of models, whereas masqueraders do not affect their models in the same way (Skelhorn et al. 2010b).

Masquerade and Behavior

Many species of masqueraders adopt characteristic postures or behaviors that might enhance their resemblance to inanimate objects. When it is windy, several species of stick insects sway from side to side when blown by wind, possibly enhancing their resemblance to the motion of twigs in the breeze (Bian et al. 2016). Twiglike larvae of the early thorn moth (*Selenia dentaria*) settle on branches where twigs are abundant and which they resemble in size.

Nonvisual Masquerade

Theoretically masquerade should also involve nonvisual mechanisms, because most organisms exist in multisensory environments. However, there is not much evidence to support this idea (Ruxton 2009). The fish *Oxymonacanthus longirostris* (Monacanthidae) feeds almost exclusively on corals, associates closely with these corals, and visually resembles a coral branch. The fish is able to chemically resemble its coral habitat by matching the odor profiles, which reduces its detectability to predators, but whether this qualifies as masquerade or crypsis is not yet known (Brooker et al. 2015).

How Did Masquerade Evolve?

Masquerading species may have evolved from cryptic ancestors (Skelhorn et al. 2010a). Animals that developed a minor resemblance to an appropriate model may have been misclassified by predators, leading to reduced attacks. Likewise, predators with a resemblance to models could cause reduced threat perception by prey. Such a resemblance would probably stem from a mutation that may also reduce the animal’s level of crypsis. However, if the benefit of being misidentified was higher than the cost of being detected, selection should favor masquerade. It is likely that the accuracy of the resemblance would then have been gradually improved by selection.

A recent comparative morphological analysis of the wing patterns of *Kallima* butterflies revealed that the leaflike wing patterns in this lineage evolved in a gradual process from ancestors that did not resemble leaves (Suzuki et al. 2014).

Conclusion

Despite a great deal of research attention during the last 6 years, there is still much to learn about masquerade. For example, there are no experimental tests of how masquerade evolves, which

leaves it an open question as to how masquerade evolves. More tests on how behavior or other sensory modalities enhance the resemblance of animals to inanimate objects would be worthwhile. Furthermore, research on the use of masquerade in predators would reveal if prey also misclassify predators as inanimate objects.

Masters and Johnson

Lora E. Adair
Lyon College, Batesville, AR, USA

Definition

Dr. William Masters and Virginia Johnson were pioneers in the scientific study of sexuality, sexual function, and sexual dysfunction. Beginning their work at Washington University (1957) and continuing their efforts at the Masters and Johnson Institute (1964), they served as one of the first research teams to systematically study the biological substrates of human sexual arousal, orgasm, and intercourse.

Introduction

“Knowledge of history brings order to disorder and imposes meaning on what appears to be chaos, putting the past into perspective to explain the present” – Schultz and Schultz (2015).

An understanding of the current state of any science rests upon the knowledge of, and appreciation for, that scientific field’s history. Specifically, understanding the history of the scientific study of sexuality and sexual behavior provides a context that unites a broad range of disciplines (e.g., evolutionary psychology, social psychology, biological psychology), all of which provide their own unique perspective to the study of

sexuality and sexual behavior. Further, this understanding of history helps to illustrate the complex ways in which scientific findings reflect the time, cultural, social, political, and economic climates during which they were interpreted and disseminated. This entry will explore the significance of the works of Masters and Johnson in constructing the current understanding of sexuality and sexual behavior, as well as the implications of their findings for the study of sex and sexuality through an evolutionary lens. This discussion will begin with (1) the lives of Masters and Johnson and (2) their influential findings, methodologies, and publications.

Masters and Johnson

The history of the study of sexuality and sexual behavior begins as early as 1886, when Richard von Krafft-Ebing published a work detailing sexuality as “the most powerful factor in individual and social existence” (p. 1), entitled *Psychopathia Sexualis*. This text exemplifies the focus of the scientific study of sexuality during the late nineteenth and early twentieth centuries: *sexual pathology* and *the perpetuation of gender stereotypes* prescribing chastity and passivity for women and aggressive, insatiable sexual appetites for men. As von Krafft-Ebing (1886) explains:

Undoubtedly man has a much more intense sexual appetite than woman. As a result of a powerful natural instinct, at a certain age, a man is drawn toward a woman. . . . In accordance with the nature of this powerful impulse, he is aggressive and violent in his wooing. . . . (p. 13)

This reflects the *Zeitgeist* of the time, wherein late-nineteenth-century European attitudes toward sex and sexuality regarded men as individuals driven uncontrollably by sexual impulses, for example, the use of the phrases “white meat” and “dark meat” to refer to poultry being served at meals became increasingly popular, as the use of words like “breast” and “thigh” was impolite as they were considered to ignite men’s sexual passions (Rosenthal 2013). Of women, von Krafft-Ebing (1886) adds:

If she is normally developed mentally, and well bred, her sexual desire is small. If this were not so the whole world would become a brothel and marriage and a family impossible. It is certain that the man that avoids women and the woman that seeks men are abnormal. Woman is wooed for her favor. She remains passive. (p. 13)

Represented herein, Victorian attitudes and expectations of women’s sexuality were extremely repressive. Women were not expected to express (or possess) strong sexual desires, and doing so was often treated as pathological (Degler 1974). Indeed, much of the early scientific study and understanding of sex and sexuality was based on the use of samples of women seeking treatment for some kind of psychological and/or physiological disturbance, dysfunction, or distress. Accordingly, the early study of sexuality emphasized pathology and dysfunction:

Mrs. V. has suffered with a passion for men since her earliest youth. . . . She loved her husband passionately, but even with him she could not keep from demanding coitus of every one with whom she could be alone. . . . (von Krafft-Ebing 1886, p. 55)

Importantly, during the mid-twentieth century, the study of sex and sexuality began to shift away from reliance upon case studies and stereotypes which perpetuated a misunderstanding of men and women’s sexuality. To begin this shift, Alfred Kinsey employed questionnaires and structured interviews to obtain a more representative sampling of human sexual behavior and sexual attitudes, publishing his work in two sequential works, *Sexual Behavior in the Human Male* (1948) and *Sexual Behavior in the Human Female* (1953). In these works, Kinsey contradicted contemporary attitudes by reporting the incidence of same-sex sexual behavior, solitary sexual practices, and sexual intercourse outside of the context of marriage in men and women (Rosenthal 2013). These narratives paved the way for the physiological study of human sexual behavior by Dr. William Masters and Virginia Johnson.

The Lives of Masters and Johnson

William H. Masters earned his medical degree at the University of Rochester in 1943, specializing in obstetrics and gynecology. His career as a sex

and sexuality researcher really began once he accepted a faculty position at the Washington University Medical School in 1947. Masters' research at Washington University began by focusing on a specific population: prostitutes. Masters observed the sexual behavior of prostitutes and conducted interviews with many women involved in sex work; arguably these experiences – quite progressive given they were taking place in the early 1950s – provided unique insights which inspired Masters' later works. For example, historical accounts of these qualitative studies suggest that Masters learned, and was surprised by, the prevalence of faked orgasm in this special population of women (Maier 2009). His structured interviews, which served to debrief sex workers after their sexual experience with a particular client, revealed that his sample believed that faked orgasm was something which often characterized women's partnered sexual experiences, in and out of sex work. Indeed, faked orgasm is prevalent in women's sexual experiences (approximately 50% of sexually active women report having faked orgasm; Muehlenhard and Shippee 2010), and evolutionary scholars propose that faking orgasm may serve the adaptive function of mate retention, particularly when the likelihood of defection or partner infidelity is high. Some attribute Masters' surprise and misunderstanding of women's experiences and perspectives regarding sexual practices with his desire to seek out and hire a female research partner (T. Maier, interview with NPR, October 4, Maier 2013). Given the unrepresentative nature of Masters' early samples, regarding the sexual experiences and attitudes of American women, these findings are largely unpublished and undocumented (Maier 2009).

Virginia Johnson first pursued her education at Drury College as a 16-year-old, but did not complete her post-secondary degree training. She returned to college at the University of Missouri to study music and pursue her ambitions to be a country singer (Fox 2013). After three marriages ended in divorce, Johnson returned to school at Washington University to pursue a degree in sociology (Hayman 2013). It was at Washington University that Masters met Johnson and employed

her as a research assistant and secretary in 1957 (Rogers 2015). Initially assisting with administrative duties, particularly facilitating recruitment of representative samples of men and women for physiological study, eventually Johnson became an equal partner in their research team and cofounded the Reproductive Biology Research Foundation (1964) in St. Louis, Missouri – renamed the Masters and Johnson Institute in 1978 (Fox 2013).

Influential Findings, Methodologies, and Publications

During their collaboration, Masters and Johnson studied the physiological substrates of sexual activity and sexual arousal in individuals aged 18 to 89 (Rosenthal 2013). They employed interview, video recording, electrocardiography, and electroencephalography methodologies to systematically study the physiological activities underlying masturbation and partnered sex with 312 males and 382 females from “the academic community associated with a large university-hospital complex” (Masters and Johnson 1966, p. 11). While this was a more representative sample, compared to early work focusing entirely on male and female prostitutes, Masters and Johnson (1966) do admit that this sample does not represent individuals of lower socioeconomic status. Using these techniques and these community samples, Masters and Johnson were among the first to (a) describe the four stages of the sexual response and (b) the treatment of sexual dysfunction.

The Four Stages of the Sexual Response

Detailed elsewhere in this work (*The Four Stage Model of the Sexual Response*), Masters and Johnson were among the first to detail the physiological stages of the human sexual response (Masters and Johnson 1966). Of note, Albert Moll's work *The Sexual Life of the Child* (1912) and Havelock Ellis' work *Studies in the Psychology of Sex* (1928) both detailed models of the physiology of the human sexual response. What was unique and revolutionary about Masters and Johnson's contribution to the study of sex and sexuality was their use of empirical methods to collect their physiological data (Rosenthal 2013).

Masters and Johnson (1966) described the human sexual response cycle as occurring in four stages, “(1) the excitement phase; (2) the plateau phase; (3) the orgasmic phase; and (4) the resolution phase” (p. 4). During the first phase, they describe a response in the presence of “any source of somatogenic or psychogenic stimulation” (p. 5) wherein physiological arousal begins to build; further, they indicate that a transition to the next phase of the response cycle is characterized by an increase in intensity of physiological arousal (due to continued stimulation). The second phase, the plateau phase, is described via this increased intensity of arousal. Continued “adequate” (p. 6) stimulation during this phase is required for the individual to achieve the third phase, orgasm.

They describe the orgasm as characterized by physiological changes in the penis, prostate, seminal vesicles, clitoris, vagina, and uterus – as well as spasms and muscle contractions observed elsewhere in the male and female body. Interestingly, they have this to say about the difference in the male and female experience of orgasm: “There is great variation in both the intensity and the duration of female orgasmic experience, while the male tends to follow standard patterns of ejaculatory reaction with less individual variation” (p. 6). This is consistent with contemporary evolutionary explanations of the female orgasm; according to the mate-choice hypothesis, the (comparatively complex) female orgasmic experience serves to evaluate the suitability and commitment of a potential long-term mate (Puts et al. 2012). During the final phase of the sexual response cycle, resolution is detailed as an “involuntary period of tension loss” (p. 6) wherein the physiological markers of arousal and orgasm have faded and time (and additional stimulation) is necessary to reinstate excitement and eventually orgasm. Of particular note to contemporary evolutionary psychology, Masters and Johnson (1966) emphasized the role of biological (rather than sociological) forces in shaping sex drives and sexual experiences: “The cycle of the sexual response, with orgasm as the ultimate point in progression, generally is believed to develop from a drive of biological-behavioral origin deeply integrated into the condition of human existence” (p. 127).

The Treatment of Sexual Dysfunction

In 1970, Masters and Johnson published their second influential work (following the publication of *Human Sexual Response* in 1966), entitled *Human Sexual Inadequacy*. This work detailed sexual function and dysfunction in geriatric populations – groundbreaking for the time of its release. Importantly, this work initiated an intellectual movement toward the de-stigmatization of sexual activity in old age – encouraging the maintenance of, and open communication regarding, sexual activity as one ages (Masters and Johnson 1970).

Furthermore, Masters and Johnson’s (1970) work revolutionized the treatment of sexual disturbance and dysfunction. Masters and Johnson admit that their work regarding sexual dysfunction uniquely reflects 5 years of study of the physiological substrates of human sexual behavior and arousal; “. . . categorically the greatest handicap to successful treatment of sexual inadequacy was a lack of reliable physiological information in the area of the human sexual response. It was presumed that definitive laboratory effort would develop material of clinical consequence” (p. 1). Although their work does indeed detail the *physiological* symptoms of vaginismus, dyspareunia, impotence, and premature ejaculation (to name a few) with reference to the physiological substrates in “normal” sexual functioning populations, their explanations for the causes of sexual dysfunction are almost entirely *psychological* (Leiblum 2007).

Prior to the publication of *Human Sexual Inadequacy*, sexual dysfunction was treated with long-term therapy performed on an individual basis. Masters and Johnson (1970) uniquely prescribed short-term (approximately 2 weeks) treatment of sexual dysfunction in joint therapy; “. . . there is no such thing as an uninvolved partner in any marriage in which there is some form of sexual inadequacy” (p. 2). So fervent was their belief in the utility (and necessity) of partnered therapeutic techniques to treat sexual dysfunction, they employed the use of “partner surrogates” for unmarried individuals seeking treatment at their clinic. As Masters and Johnson (1970) explain, “. . . a partner to share the patient’s concerns for

successful treatment, to cooperate in developing physically the suggestions presented during sessions in therapy. . . (is) essential, if effective sexual functioning is to be returned to" (p. 147).

Conclusion

Understanding the history of the scientific study of sexuality and sexual behavior provides a context that unites the many perspectives, and theoretical approaches, to the study of sex. In this entry, the ways in which scientific findings and clinical practice have reflected the Zeitgeist of the time have been detailed – with particular emphasis being given to the work of scholars which paved the way for the first systematic, physiological study of sexual function and dysfunction by Masters and Johnson. Contemporary understandings of the physiology of the human sexual response, the sexual interests and needs of geriatric populations, and the efficacy of fast, coupled therapeutic treatment of sexual dysfunction were made possible by the work of Masters and Johnson. Perhaps most importantly, during a time characterized by stereotype, taboo, and misunderstanding, Masters and Johnson turned a clinical and scientifically rigorous eye to the American bedroom.

Mate Choice Copying

[Mate preference copying](#); [Social learning in mate choice](#); [Social learning of mate preferences](#)

Definition

Strictly, mate choice copying occurs when an observer views a target with a mate and the target is more likely to be chosen as a mate by the observer because of the presence of the current mate. More broadly, the phenomenon is related to social learning of mate choice and preferences whereby information about the target's mate, or the absence of a target's mate, affects an observer's preference for and potential choice of the target.

Introduction

It is extremely unlikely that we are born with a template for the ideal mate. Indeed, mate preferences in humans can be learned and change with experience. One source of learning comes from the social domain: observing other people's preferences and partnerships. In recent years, a

number of studies have highlighted social learning effects in women's mate preferences and mate choice.

Why would women be interested in the mate choice of others? There are of course time and energy costs to sampling a range of partners, but there are also major costs to poor mate choice decisions, such as desertion or infidelity. We would then expect individuals to choose their partners carefully using all available information, and information about the choices of other's is presented all around us. In fact, learning from others is common in many domains, and evolutionary selection for social learning mechanisms can occur when there are costs to acquiring accurate behavioral information via individual learning (Richerson and Boyd 2005). Mate preference and choice are therefore a prime domain for social learning as using information about other's choices is a low cost and low risk means to learn who is and who is not likely to be a good partner without the time and effort needed to learn individually by dating and mating with each potential partner. Following or copying other's choices allows an individual to assess potential mates more quickly and efficiently than through individual trial and error as well as avoiding the potential costs associated with poor choices.

Copying

Mate choice copying, whereby individuals are more likely to select mates if that mate has been observed as a mate with a member of the opposite sex, has been observed among females in a wide range of nonhuman animals, including fish and bird species (Galef and Laland 2005). These studies have generally shown that in choice tests where females observe another female (the "model") to be paired with one of two males (the "targets"), female observers are subsequently more likely to prefer the target male they had seen paired over the male they had seen unpaired (Hoglund et al. 1995).

Humans also appear to be very interested in the partnerships of other's. For example, celebrity

gossip magazines and websites often focus on new and failed partnerships. But do women “copy” the partnerships of others like other animals? Inspired by work on nonhuman animals, research suggests that social learning may also influence human mate preferences (for review, see Little et al. 2011) but perhaps in a more sophisticated way than simple copying.

Some studies have manipulated cues to relationship status to examine how this impacts on men’s attractiveness. While some research has shown that the presence of wedding rings on men did not increase women’s preferences for those men, other studies have found that images of men labeled as married were more attractive than those labeled as single (for review, see Little et al. 2011). These results do not suggest a strong pattern of following the choice of other women; however, cues to current marriage in fact may be problematic. For example, while it is predicted that having been chosen as a partner would make a man more attractive, marriage sends a signal that the man may be off the market and unavailable and, at least, that a woman would have to compete with a current wife. Given humans engage in long-term monogamous relationships, being married may indeed indicate a man is attractive to other women, but any increased attraction may be counteracted by the fact that the man is already committed to another woman.

More subtle cues to other women’s preferences show more consistent evidence that women follow the preferences of other women. For example, one study has shown that women appear to follow the preferences expressed by other women for men. Women prefer pictures of men if presented alongside images of other women who look at the target man with positive smiling expressions compared to more negative neutral expressions (Jones et al. 2007). In a more naturalistic study, after observing real interactions on a video recorded during a speed dating event, women were more interested in men they perceived as having a successful date (Place et al. 2010). Women therefore appear to mimic the attitude of other women to particular men.

Bias in Social Learning of Preferences

Another factor in learning from others is that some individuals may be better models than others – women may be more likely to attend to information about partner choice and preferences from particular women. Again, this may be important in explaining why simply being married is not a sufficient cue to be deemed a good likely partner. If a man’s wife was unattractive and disagreeable, perhaps the man himself has negative qualities. In this way we can expect social learning to be biased toward certain models: “model-based biases.”

But which models should women attend to help guide their choices? Models who have greater available choice might make the best models. Attractive women, for example, can select from a variety of men, and so it follows that their choices may be weighted more highly than the choices of less attractive women who may have more limited choice. Indeed, there is evidence to suggest that women attend to the attractiveness of a man’s current purported partner. Sigall and Landy (1973) used real individuals to show that positive characteristics are attributed more frequently to men who are paired with attractive rather than unattractive women. In this way they show that an attractive partner may “radiate beauty.” Such a phenomenon is suggestive of a sophisticated form of mate choice copying, whereby women can use the attractiveness of a partner that a man can acquire in order to judge the man’s own attractiveness. A more recent study using images that were presented with a fictitious partner has shown that both men and women find a face paired with an attractive partner to be more attractive than one paired with an unattractive partner for a long-term but not a short-term relationship (Little et al. 2008). Effects specific to long-term preferences in humans suggest that social information is being used to infer non-physical traits that make a target a good long-term partner, such as resources or intelligence, which may be difficult to determine from physical appearance alone.

Prestige-Biased Learning

Alongside attractiveness, we might also expect popular women to have greater choice, and certainly we see that people look up to prestigious and popular individuals. It has been suggested that prestige evolved from social learning strategies to identify appropriate models from whom to learn and that we preferentially attend to prestigious models. If others consider someone prestigious, then it might be assumed they are useful model for social learning. One study has shown that men are rated as more attractive by women if they are presented with fictitious partners who are believed to be popular in their peer group than if they are believed to be less popular in their peer group (Little et al. 2015).

Effects of Age of Learner

It may be useful to attend to those with the most choice and those who are prestigious, but it is also useful to attend to individuals with the most information. Another model bias has been observed in fish species whereby young guppies are more likely to copy the mate choice of older models than younger models (Dugatkin and Godin 1993). Older guppies are also less likely to be influenced by the choices of younger females (Dugatkin and Godin 1993). In humans, it is likely that as women get older, they have a greater store of knowledge about the quality of potential mates. This greater experience means that older individuals should be less susceptible to social influences, relying more heavily on their own knowledge rather than the choices of younger, less experienced women. This suggests that the balance of social learning is not stable across the lifespan and social learning effects may have their greatest influence when observers are young and relatively inexperienced: women may use social information when uncertain but use individual knowledge when they have relevant experience. In line with these arguments, younger women have been found to be more influenced by the choices of other women than older women in terms of mate preferences (Little et al. 2015).

Conclusion

In conclusion, a number of studies support the idea that women learn about mate preferences and choices from observing the preferences, attitudes, and choices of other women. There appear to be a number of sophisticated biases in humans that move beyond simple mate choice copying, such as preferential attention to the mate choices and preferences of attractive, prestigious, and older models. The social transmission of mate preference highlights the flexibility of women's preferences and the complex mechanisms that determine who we find attractive.

Definition

By suppressing ovulation, hormonal contraceptives alter men's and women's mate choices that depend on women's menstrual cycles.

Introduction

Men's and women's mate choices (i.e., mate preferences) vary according to the normal hormonal fluctuations associated with women's ovulatory cycles. Hormonal contraceptives, however, suppress ovulation by altering these normal hormonal fluctuations and thus affect men's and women's stated mate preferences. This entry will describe the (a) extent to which women's hormonal contraceptive use alters their mate preferences, (b) extent to which women's hormonal contraceptive use alters men's mate preferences, and (c) implications of these mate-preference alterations for men's and women's long-term relationships.

Hormonal Contraceptives Disrupt Women's Mate Preferences

A robust body of research demonstrates that women's mate preferences change across the ovulatory cycle (for a review, see Gildersleeve et al. 2014; for an alternative perspective, see Wood et al. 2014). For example, naturally cycling women demonstrate stronger preferences for cues of male genetic quality (e.g., masculinity, symmetry) near ovulation compared to less-fertile phases of their ovulatory cycles (Meltzer 2016; for a review, see Alvergne and Lummaa 2010; Gildersleeve et al. 2014; Little et al. 2008). Likewise, naturally cycling women display greater sexual attraction and responsiveness to mates whose major histocompatibility complex (MHC) genotype differs from their own MHC genotype near ovulation compared to less fertile phases of their ovulatory cycles (Garver-Apgar et al. 2006). The MHC genotype is a genetic marker of immune functioning, and mating with dissimilar-MHC partners can result in increased variability among and immunocompetence of offspring. Thus, women may reproductively benefit to the extent that they experience increased attraction to such mates at a time when they are most likely to conceive (i.e., ovulation). Moreover, naturally cycling women demonstrate a stronger preference for facial cues of health (e.g., pallor) in potential

mates during the luteal phase of their ovulatory cycles (i.e., when progesterone levels are highest and women's bodies are preparing for pregnancy; Jones et al. 2005). Notably, such facial cues may be indicative of men's immune system strength, and mating with such immunocompetent men would be beneficial for potential offspring.

Researchers have recently demonstrated, however, that women's hormonal contraceptive use can shift these preferences. Indeed, women who use hormonal contraceptives show weaker preferences for facial and vocal masculinity (for a review, see Alvergne and Lummaa 2010) and behavioral masculinity (Meltzer 2016), suggesting that hormonal contraceptives interrupt women's preference for masculine men (but also see Jones et al. 2018). Likewise, women who use hormonal contraceptives demonstrate a stronger preference for MHC-similar mates (Roberts et al. 2008) rather than MHC-dissimilar mates. Given the benefits associated with partner masculinity and MHC dissimilarity, such shifts in women's mate preferences could have negative consequences for offspring fitness. Interestingly, women who use hormonal contraceptives demonstrate a stronger preference for men's facial cues of health than do naturally cycling women – likely because hormonal contraceptives elevate women's progesterone and it is hypothesized that progesterone increases women's attraction to facial cues of health.

Hormonal Contraceptives Disrupt Men's Mate Preferences

Scholars previously posited that because women's ovulation is concealed, men's psychological processes (including their mate preferences) are not affected by women's ovulatory cycle. Recent empirical evidence, however, demonstrates that this may not be the case – there are subtle cues of women's fertility such as appearance, scent, and voice that influence men's mating behaviors, including men's preferences for and perceptions of women. For example, men report greater physical attraction to ovulating women (compared to less fertile women; for a review, see Alvergne and

Lummaa 2010), and they treat such women differently (Miller et al. 2007). Indeed, in a study of exotic dancers, men provided greater monetary tips to dancers near ovulation versus less fertile phases of their menstrual cycle (Miller et al. 2007). Likewise, men rate the scent of ovulating women as more attractive than non-ovulating women (Kuukasjärvi et al. 2004) and exhibit physiological changes such as elevated testosterone following exposure to the scent of ovulating women (Miller and Maner 2009). Additionally, men report an increased preference for women's voices near peak fertility compared to less fertile phases of the ovulatory cycle (for a review, see Alvergne and Lummaa 2010).

Recent research, however, has demonstrated that hormonal contraceptives indirectly alter these preferences. For example, men do not demonstrate an increased attraction to or preference for the mid-cycle scent (Kuukasjärvi et al. 2004) or voice (Alvergne and Lummaa 2010) of women using hormonal contraceptives. Additionally, in that study of exotic dancers, men did not provide greater tips mid-cycle to dancers who were using hormonal contraceptives (Miller et al. 2007). Together, this evidence suggests that women's hormonal contraceptive use influences men's mate preferences by suppressing women's naturally fluctuating hormones and thus the subtle cues of fertility associated with those hormones.

The Implications of Women's Hormonal Contraceptive Use for their Long-Term Relationships

The extant evidence clearly suggests that women's hormonal contraceptive use alters both men's and women's mate preferences and thus may have implications for the mates they choose. If this is indeed true, then women's hormonal contraceptive use could also have lasting implications for long-term relationships. Some empirical evidence is consistent with this notion.

Long-term relationships are long lasting and typically characterized by high levels of commitment. Given women's increased preference for and attraction to men who display cues of genetic

quality (e.g., masculinity, symmetry, MHC dissimilarity; Alvergne and Lummaa 2010; Garver-Apgar et al. 2006; Little et al. 2008), women are most satisfied to the extent that their long-term mates display such cues (e.g., Meltzer 2016). Because these preferences are muted among women who use hormonal contraceptives, however, there may be unintended consequences for women's long-term relationships. Many women begin long-term relationships while using hormonal contraceptives and thus choose their long-term partners while using hormonal contraceptives. But at some point during their relationships, women often discontinue using hormonal contraceptives in order to conceive. Other women, in contrast, choose their long-term partners while not using hormonal contraceptives and at some point during the relationship begin using hormonal contraceptives as they become sexually active. Any changes in preferences for partner genetic fitness associated with such changes in hormonal contraceptive usage may have implications for men's and women's long-term relationships.

Empirical evidence supports this notion. Women who use hormonal contraceptives when they meet their long-term partners and later discontinue those contraceptives report lower sexual satisfaction (Roberts et al. 2014) and relationship satisfaction (Russell et al. 2014) compared to those women who meet their long-term partners while using hormonal contraceptives and continue using those contraceptives (but also see Jern et al. 2018). Interestingly, the association between women's congruency in hormonal contraceptive use and relationship satisfaction depends on their long-term partners' facial attractiveness – women who meet their long-term partners while using hormonal contraceptives and later discontinue those contraceptives report increased relationship satisfaction if their partners have more attractive faces, but they report decreased relationship satisfaction if their partners have less attractive faces (Russell et al. 2014). This finding supports the notion that hormonal contraceptives influence women's long-term relationships because they potentially influence who women select as long-term partners.

Summary

Men's and women's mate preferences fluctuate across women's ovulatory cycles. Specifically, women demonstrate a mid-cycle preference for masculine and symmetrical men, and men demonstrate a preference for and increased attraction to ovulating women compared to less fertile women. Notably, these preference shifts likely have implications for the long-term partners that men and women choose. Hormonal contraceptives, however, suppress ovulation in women and consequently interrupt these effects. Taken together, this growing body of research suggests that hormonal contraceptives interrupt the evolved psychology of attraction, which may have maladaptive implications for offspring fitness and relationships in general.

Definition

Choosing a romantic partner in part or wholly based on information provided via others' preferences and choices rather than relying solely on one's own judgment about the attractiveness and suitability of a potential mate.

Introduction

Choosing a mate is a complex decision for an individual to make: there are myriad personal characteristics that potential mating partners possess which can each affect the chooser's fitness. Some of these characteristics are physical traits which indicate high genetic quality, such as bilateral symmetry and cues to sex hormone levels. Others include a potential mate's likely ability to negotiate their social world to their own benefit and to secure food and other resources. The large number of personal attributes that must be weighed-up in mate choice decisions means that individuals are likely to vary in their skill at choosing the best partner. The best partner in an evolutionary context is defined as the partner who through genetic, parenting, resource and other contributions will maximize the chooser's reproductive success. To make mate-choice decisions even more difficult, some desirable traits are not easy to observe directly: it is difficult to acquire information about personality traits that may contribute to offspring survival and success. For these reasons, evolutionary biologists hypothesized and

Mate Competition

- ▶ [Intrasexual Violence and Aggression](#)
- ▶ [Parental Investment and Sexual Selection](#)

mathematically modeled whether fitness could be maximized by choosing the partner that *other* individuals select as the best partner (mate-choice copying), even if they have made the wrong choice and chose a lower quality partner through copying rather than making an independent assessment. These mathematical simulations suggested that copying others' mate choice decisions can evolve even in cases of mistakenly copying someone who has made a poor choice, because the worst case scenario is that a mate-choice copier will only do as badly as their reproductive competitor (Losey et al. 1986).

Evidence for Mate-Choice Copying

Field research on mate-choice copying began in the 1970s, and by the 1990s evidence had shown that mate-choice copying occurs in a diverse array of birds and fish (reviewed in Witte et al. 2015). Most of this research focused on females copying other females, because in most of the species being studied females were choosier than males about mate quality (Bateman's principle). Early research was typically through field observational studies, but by the 1990s experimental research designs were commonly used to demonstrate mate-choice copying. In fish, experiments could be done by partitioning aquariums using clear plexiglas so that a courting or mating pair could be placed in close proximity while another potential mate was placed in the aquarium in a position that made them appear as the less-preferred male. Partitions would then be removed to assess whether females who were observing the situation were more likely to select the male who appeared to be the preferred partner (Dugatkin 1992). The convention in experimental mate-choice copying studies is to term the individual who is observing and will potentially copy another's choice the "observer" or "focal" female, the individual who is in a position to be copied is the "model," and the opposite sex individual is the "target."

The first published study in humans to directly address mate-choice copying was on what is colloquially called "the wedding ring effect", which is the idea that women prefer men who by wearing

a ring are signaling that they have been chosen for a long-term relationship and are likely to be capable of long-term commitment. The authors failed to find a female preference for men wearing a wedding ring, although this was hypothesized to be because marriage is a legal commitment that is difficult to dissolve (Uller and Johansson 2003). Most researchers studying mate-choice copying in humans have used picture-based preference methods modeled more closely on the experimental study designs being used in non-human research. For example, photos of pairs of models and targets were presented to observers as dating couples. These, and more realistic video-based study designs, demonstrated that humans too appear to mate-choice copy (Waynforth 2007; Jones et al. 2007; Yorzinski and Platt 2010), and that men mate-choice copy (Place et al. 2010), which mirrors recent theory and findings in non-humans: males mate-choice copy when they play a large role in parental care, and hence have more to lose by making a poor mate-choice decision. However, male mate-choice copying may have a lower fitness payoff for copiers if it increases competition for sexual access and sperm competition (Witte et al. 2015). Human mate-choice copying studies have demonstrated that not all individuals are equally prone to copying, for example, women who are younger and those with less sexual experience are more likely to copy (Waynforth 2007; Place et al. 2010; Little et al. 2015), and observers who are more physically attractive than the model and target are less likely to copy (Place et al. 2010; Yorzinski and Platt 2010; Little et al. 2015).

Conclusion

Although to date there is no published meta-analysis, there is growing evidence that humans mate-choice copy, and that it is a variable or facultative behavior depending on a number of factors, such as lack of prior sexual experience. Mate-choice copying research continues to develop into new avenues. One of these is whether individuals exploit mate-choice copying to deceive their competitors by serenading potential

partners who they do not prefer (Witte et al. 2015). Copying others' decisions is by no means limited to mate-choice. One example is following political leaders, where it has been suggested that the personal attributes and experience of a leader are less important in people's decisions about which politician to follow than evidence of others' support and enthusiasm for a leadership candidate: people copy each other's preferences for leaders rather than weighing-up their leadership abilities (Spisak et al. 2011).

Mate Deprivation Hypothesis

Burak Doğruyol
Psychology Department, Altınbaş University,

[Male sexual coercion](#)

Definition

An evolutionary hypothesis explaining males' sexual coercive behaviors driven by limited access to potential mates.

Evolutionary perspectives provide various explanations for males' sexual coercive behaviors including physical and psychological abuse and physical and psychological aggression. Among them, rape as a specific form of physical aggressive behavior has been evaluated in the context of evolved psychological mechanisms and behavioral strategies to increase reproductive success. Within numerous attempts to explain rape, two different lines of accounts to rape in the evolutionary framework occur. According to one line, rape is an indirect (mal)adaptation or by-product of something else such as promiscuous sex (Symons 1979). Besides, rape is assumed to be a direct adaptation and an evolved mechanism to

maximize reproductive success. Direct adaptation perspective, therefore, implies that rape should be selected in our ancestral past because it results in successful reproduction.

Mate deprivation hypothesis (Thornhill and Thornhill 1983, 1991, 1992) asserts that rape is a specialized conditional mating strategy to maximize reproductive success. Thus, as an evolved mechanism, all males have the potential to use sexually coercive behaviors under certain conditions. Those conditions are defined as limited access to potential partners as a result of environmental and developmental forces such as lack of status, wealth, and/or physical attraction. Therefore, disadvantaged males in the competition to access mates use sexually coercive behaviors to maximize their reproduction success. Research on other animal species displaying sexual coercive behaviors provide indirect support for the hypothesis that rape is an evolutionary adapted behavioral strategy (e.g., Galdikas 2005). Furthermore, Thornhill and Thornhill (1983) reported that arrested rapists are more likely to belong to low socioeconomic status. In another study, it was also found that males from lower socioeconomic status are more likely to rape; besides, those males have higher learning disabilities and psychological disorders (Figueredo et al. 2000). Thornhill and Thornhill (1992) further argue that if rape is an adapted mechanism, then as an implication, sexual coercive behaviors should be arousing. Results of their studies with rape victims and offenders supported this claim (Thornhill and Thornhill 1992). Related to this, it is suggested that sexual coercion and/or female rejection to sexual attempts would not interfere with the sexual desire and performance (Thornhill and Palmer 2000). On the contrary to supporting evidence, some other theorists claim that the hypothesis currently lacks sufficient empirical support. For instance, rape is not a unique behavior for low socio-economic status males; rather rape instances can be found on all segments of status. Likewise, males belonging to low socioeconomic status are more likely to commit lots of different kinds of crimes (e.g., Alexander and Culligan 1979). Besides, mate deprivation hypothesis implies that since rape is

an adaptation to scarcity to reach mates, then males who commit rape should be relatively unsuccessful in their history to reach mates and sexual intercourse. However, it was found that males who commit more sexually coercive behaviors reported higher numbers of sexual intercourse history (Lalumiere et al. 1996). Besides, sexually coercive males in the same study reported more preference for multiple partners and casual sex suggesting that sexual coercion is used as an extreme short-term mating strategy instead of deprived access to mates. Kanin (1985) reported that sexually coercive males are more sexually deprived not because of limited access but because of higher anticipation which results in sexual frustration.

Marital Satisfaction

Marriage is considered a reproductive union where love is pursued between two individuals. It is seen in every culture around the world (Brown 1991; Buss 1985; Buss and Schmitt 1993; Epstein and Guttman 1984; Shackelford and Buss 1997; Vandenberg 1972). This marital union is a complex state where two individuals tend to share space and begin to have one common life. Also, couples that are satisfied tend to stay together. Shackelford and Buss (1997) report that marital satisfaction is an adaptive function designed to help individuals determine if their relationship is a long-term relationship that should continue. Several factors influence marital satisfaction. From an evolutionary perspective, mate value discrepancies, infidelity, personality attributes, some mate guarding tactics, and abuse affect marital satisfaction (Shackelford and Buss 1997). Also, men's marital satisfaction is influenced by their partner's attractiveness.

Meltzer et al. (2014) report that men with attractive wives have higher marital satisfaction. When couples are dissatisfied, mate expulsion often occurs. For married couples, mate expulsion often takes the form of divorce. Divorce is largely universal, occurring in both industrialized and non-industrialized cultures (Betzig 1989; Marlowe 2010; Anderson et al. 2011). But, mate expulsion can also occur for non-married couples. That mate expulsion takes the form of a breakup since there is no union that has to be legally dissolved.

Frequency of Divorce and Breakups

Mate expulsion in the form of divorce in the USA occurs in 70% of marital relationships (Shackelford 2001). The divorce rate is so high because mate expulsion is adaptive. Mate expulsion allows a couple to end a relationship where the costs exceed the benefits and find a relationship with a different partner that provides more benefits than costs rather than worry about the reputational costs that may be associated with staying in a bad relationship and committing infidelity. This allows individuals to maximize their fitness (Shackelford and Buss 1997). There are sex differences in decisions to divorce also. Since women bear more biological costs in relationships and are choosier with respect to selecting mates (Bailey et al. 1994; Buss 2003), women are more likely to initiate a divorce (Brinig and Allen 2000).

Mate expulsion in non-marital relationships is also very common (Battaglia et al. 1998), and consistent with evolutionary theory, women are more likely to initiate the mate expulsion (DeLecce and Weisfeld 2016).

Infidelity and Mate Expulsion

Jealousy within a couple can be a potent indicator of dissatisfaction with the relationship. Men tend to be jealous and worry about their partners committing sexual infidelity, while women tend to be

jealous and worry about a partner's commission of emotional infidelity (Buss et al. 1992). Not surprisingly, infidelity in married couples is a leading contributor to divorce (Amato and Previti 2003; Scott et al. 2013). This occurs because our evolved sex differences in mating and parental investment are evoked which leads to becoming distraught over different forms of infidelity (Buss et al. 1992; Tagler and Jeffers 2013).

Emotional and Sexual Infidelity

Since women are the choosier sex because they need a higher parental investment from men (Trivers 1972), women tend to seek men who are good financial providers, stable, and emotionally supportive (Buss 1989; Li et al. 2002). So, women are more upset over a partner's commission of emotional infidelity (Wiederman and Kendall 1999) as a male's emotional connection with another woman can lead to a loss of resources and stability from the said male partner (Shackelford et al. 2005).

Since men invest primarily at the genetic level and worry about paternity certainty (Trivers 1972), men are more upset by a partner's commission of sexual infidelity. Female sexual infidelity can lead to a man being cuckolded and the maximization of another man's fitness. A partner's commission of these respective types of infidelity can lead to mate expulsion also.

Forgiveness, or Mate Expulsion

Depending on the type of infidelity committed by a partner, forgiveness or mate expulsion can occur. Since men are more upset by a partner's commission of sexual infidelity, men find it more difficult to forgive their partner if their partner committed sexual infidelity and are more likely to expel their mate for committing sexual infidelity rather than for committing emotional infidelity. Because a partner's commission of emotional infidelity is more upsetting to women, women find it harder to forgive a partner for committing emotional infidelity and are more likely to expel a mate if the mate committed emotional infidelity rather than if the mate committed sexual infidelity (Shackelford et al. 2002).

Access

Emotional and Sexual Access

Emotional access and sexual access each play a role in mate selection. Men seek and desire female partners who are willing to have sex with them (Buss 1989; Buss and Schmitt 1993). Thus, Buckle et al. (1996) and Betzig (1989) report that men place a premium on a woman's capacity to reproduce. Consistent with this, Shackelford and Buss (1997) report that competition among men for sexual access to reproductively valuable women is more intense than competition among women for reproductively valuable men. Therefore, perhaps not surprisingly, Sprecher and Cate (2004) report that men are less satisfied overall when their wives are sexually withholding. Similarly, Buss (1989) reports that men report the greatest anger and upset over women who accepted resources from them but did not provide sexual access in return. Consistent with this, Felmlee et al. (1990) report that sexual intimacy is a positive predictor of relationship steadiness. Further support for the importance of sexual access is the fact that marriages that involve successful reproduction are more likely to continue (Becker et al. 1977; Waite and Lilliard 1991), and some societies allow mate expulsion, that is, divorce, on the basis of a partner's refusal to have sex (Betzig 1989).

Women typically desire a long-term commitment from a male partner, and commitment is a product of emotional involvement (Buss et al. 1992). So, women seek and desire men who are willing to share their feelings/show they care or are committed, i.e., they are emotionally accessible. Since sexual and emotional accessibility are important for men and women, respectively, these factors should play a role in mate expulsion decisions.

Wade and Brown (2012), using scalar measures, found that women were most likely to expel their mates when their partner was emotionally inaccessible 90%, 80%, 70%, and 60% of the time, and men were more likely to expel their mates when their mates were sexually inaccessible 60% of the time. Similarly, Wade and

Mogilski (2013) examined the role of sexual and emotional access in mate expulsion using conjoint analysis and report that men are most likely to expel a mate when there is a low level of sexual access and women are most likely to expel a mate when there is a low level of emotional access; and overall, sexual access is more important for men's mate expulsion decisions than for women's mate expulsion decisions and emotional access is more important for women's mate expulsions decisions than for men's mate expulsion decisions.

Sexual Conflict

Frequency of Sex and Sexual Satisfaction

Sexuality in personal relationships results from an underlying motivation to maximize the transmission of one's genes to succeeding generations (Sprecher and Cate 2004). Thus, Americans consider sex an essential element of relational intimacy that is crucial for ensuring longevity (Michael et al. 1994; Rubin 1990). Thus, sexual intercourse is extremely important. Engaging in sexual intercourse has a significant and positive effect on relationship stability (Simpson 1987). Consequently, as Elliott and Umberson (2008) report, sexual activity in the context of long-term heterosexual relationships may be an important site of relationship vitality and conflict. Sexual frequency is also important. Call et al. (1995) report that a higher frequency of sex is associated with a happier marriage, and happier marriages are less likely to lead to mate expulsion. Furthermore, Sprecher and Cate (2004) report that large discrepancies between the desired and actual frequency of sex are associated with lower relationship satisfaction, and Blumstein and Schwartz (1983) report that this applies to all couples. Similarly, Hunt (1974), Laumann et al. (1994), and Trussell and Westoff (1980) report that couples who have a higher frequency of sex are more sexually satisfied. Thus, sexual satisfaction is also important. Sprecher and Cate (2004) point out that when individuals are satisfied sexually within their relationships, the relationships are more likely to be committed and to continue.

Mate expulsion should be less likely when couples are sexually satisfied, i.e., when there is no sexual conflict.

Most individuals in committed relationships are sexually satisfied. Laumann et al. (1994) report that 88% of married respondents report being extremely physically pleased in their relationships. Similarly, Greeley (1991) reports that one third of respondents report a very great deal of satisfaction from their sexual relationships. Both dating and married couples who are sexually satisfied also report high levels of overall satisfaction with their relationships (Blumstein and Schwartz 1983; Byers et al. 1998; Cupach and Comstock 1990; Davies et al. 1999; Edwards and Booth 1994; Henderson-King and Veroff 1994; Sprecher 2002). Additionally, White and Keith (1990) report that sexual problems or dissatisfaction at one point in marriage are positively associated with the likelihood of divorce later. Similarly, Long et al. (1996) report that sexual conflict is negatively related to sexual and relationship satisfaction. Love, commitment, and the likelihood that a relationship will last are also positively associated with sexual satisfaction (Aron and Henkemeyer 1995; Grote and Frieze 1998; Pinney et al. 1987; Sprecher 2002; Sprecher et al. 1995; Sprecher and Regan 1998; Waite and Joyner 2001; Yela 2000). Not surprisingly, then, changes in sexual satisfaction lead to changes in relationship satisfaction (Sprecher and Cate 2004) which then can lead to mate expulsion.

Definition

Mate poaching is engaging in premeditated behaviors to attract either short-term or long-term mates by luring them away from their already established relationship.

Introduction

Generally, mate poaching refers to behaviors whereby one attempts to romantically attract an individual away from an existing monogamous

relationship. Mate poaching has been defined in two different ways in the literature, with the second definition serving as a clarification of the first definition. Schmitt and Buss (2001) originally defined mate poaching as the process of romantically attracting someone who is already in a relationship. However, Davies et al. (2007) pointed out that Schmitt and Buss' (2001) definition allowed for an overestimation of the frequency of mate poaching, because it did not specify two important criteria that are necessary for mate poaching to have occurred. Davies et al. (2007) stipulated that the relationship must be exclusive such that sex with an individual other than one's partner invalidates the relationship, and poachers must know that the relationship they are poaching from is exclusive. Thus, Davies et al. (2007) revised the definition of mate poaching such that it is said to occur when a person has attracted, or tried to attract, a mate whom they know is already in an existing exclusive relationship, in order to form a new sexual or romantic relationship. Further issues related to definition are discussed by Davies et al. (2019).

It is helpful to distinguish mate poaching from other forms of romantic attraction. Mate poaching is distinct, because it presents costs that are not found during typical, early stages of relationship initiation or romantic attraction. For example, in addition to the potential rejection by the person one approaches, the person's mate may learn of the attempted poaching and seek retaliation. These costs are further discussed in the following sections. Mate poaching also entails a specific set of personality characteristics, which are presented in an upcoming section.

Evolutionary psychology offers a way to make sense of mate poaching. Mate poaching is a form of nonindependent mate choice that is an adaptive solution to the problem of locating a mate of suitable quality from the local pool of those whom are currently available. For men, this problem is thought to have been frequently occurring in ancestral environments where women, in particular, were mated early in life, pregnant much of their lifetime, and/or in situations involving polygyny where a few men dominated local mating contexts. For women, it would have been an adaptive solution to issues around resource

control, such that women could try to invade an existing relationship to secure a mate with ownership of limited resources. Those resources, in turn, may positively have impacted on their ability to successfully bear and raise children, thereby improving their reproductive success and fitness.

Putting all of these ideas together creates an interesting and unique mating-related situation. Mate poachers (i.e., those who poach someone's mate) are theorized to engage in premeditated behaviors to attract either short-term or long-term mates via luring them away from their already established relationship (Moran and Wade 2019; Schmitt and Buss 2001). Mate poaching involves covert behaviors and indirect tactics, unlike other forms of romantic attraction, due to the potential risks involved in luring an already involved mate. Furtive glances, moving into one's social network, and encouraging the target to realize the problems and dissatisfaction with their existing relationship are examples of the sorts of covert behaviors a poacher may perform. The discrete nature of romantic attraction is key, as direct flirting may lead to violence by an existing partner and be seen as in poor taste by the general social community (e.g., Schmitt and ISDP 2004). Of these various strategies of mate poaching, becoming the intended poachee's friend is viewed as a very effective strategy which mitigates risk. However, individuals who use that strategy are perceived by others as less warm, less nurturant, and less friendly than those who merely make the acquaintance of the poachee (Mogilski and Wade 2013).

Occurrence and Prevalence

Estimates regarding the prevalence of mate poaching vary, partly due to whether it is examined with respect to whether one attempts to lure a short- versus long-term mate, or whether it includes any experience versus frequent experience. For example, in a sample of US college students and older adults (average of 41 years), Schmitt and Buss (2001; study 1) report over 70% had experience in attracting an already involved partner, with about equal experience in attracting short- versus long-term mates. Almost 30%

reported frequently trying to attract long-term mates, while 10% frequently attempted to attract short-term mates. Mate poaching specifically, though, was lower, with about 50% having some experience in short- or long-term relationships, with few stating they had frequent attempts. Their sample reported that rate of poaching toward oneself was higher, with an estimated 85% of people reporting someone had attempted to poach them (Schmitt and Buss 2001).

There are some noteworthy sex differences. Schmitt and Buss (2001) found men (60–64%) are more likely to have attempted to poach a short-term mate than women (38–49%, depending on age). As an interesting aside, they reported that mate poaching tactics are perceived to be less effective when one attempts to infiltrate an existing highly committed relationship compared to less committed relationships.

Davies et al. (2007) argued that these frequencies from Schmitt and Buss (2001) may be overestimates due to differences in their definition. They later reported their sampling procedure may also be responsible; using a similar procedure, Davies et al. (2019) found no significant difference in frequencies, as compared Schmitt and Buss (2001).

In addition to the possible causes of variation in prevalence already mentioned, geographic location (as a proxy for culture) is an important consideration. Across a large sample (i.e., 53 nations, almost 17,000 participants), Schmitt and members of the International Sexuality Description Project (2004) found mate poaching was most common in Southern Europe, South America, Western Europe, and Eastern Europe and was relatively infrequent in Africa, South/Southeast Asia, and East Asia. Men were more likely than women to report having made and succumbed to short-term poaching across all regions, but the differences between men and women were often smaller in more gender-egalitarian regions. That is, similar to the rates reported using the US samples, Schmitt et al. (2004) document around 62% of men and 40% of women have attempted to attract someone who was already in a relationship with someone else for a short-term sexual relationship. However,

they argue that cultural differences exist: short-term poaching is less among East Asian men (around 29%), and under 30% for women from Middle East, Africa, South/Southeast Asia, and East Asia. Men seldom engage in long-term mate poaching, with rates higher for women, although there are cultural differences in effects due to sex (i.e., Oceania shows minimal difference whereas Africa shows large differences).

Those who attempt to mate poach tend to be moderately successful at a rate of 65% or higher (Schmitt et al. 2004, Table 4). Women are generally more successful at short-term mate poaching than men (particularly in Western Europe; 90% vs. 84%) but typically not significantly so, with the exception of Africa that shows the reverse trend (65.9% vs. 78.6%). The occurrence and prevalence of poaching for long-term relationships is similar for men and women, with no significant sex differences except for South America where more men report it ever happening (86% vs. 72%), and happening more often. They also found that about 70% of the sample worldwide reported receiving someone's mate-poaching attempt.

Some scholars document minimal sex differences in prevalence rates of mate poaching, which is in contrast to the abovementioned research findings. While the literature on infidelity shows men report higher rates than women, poaching is reported nearly equally by the sexes. However, women, but not men, may show a distinct, increased interest in men who are involved in a relationship. That is, Parker and Burkley (2009) suggest mate copying may be a possible explanation for women's interest in mate poaching. Their experimental evidence shows men are interested in women to the same degree regardless of whether they are single or not, while single women are more interested in pursuing men who are attached than single. By engaging in mate copying, women are ensuring that the mate has been "pre-screened" for quality, resourcefulness, and willingness to commit to a family life, by another woman. This finding does not imply that men are immune from mate copying; Moran and Wade (2019) report that men are more likely to engage in mate copying when a couple is

composed of a man who is more attractive than his partner. This pattern occurs because men view the woman in this couple as possessing very high qualities since she was selected by this highly attractive man. Finding and starting a relationship with a woman with characteristics similar to the woman in this couple would potentially confer benefits to the male copier's future offspring.

Costs Associated with Mate Poaching

Mate poaching is a form of mating competition, and as such, it can lead to various forms of retaliation from the person who loses the mate. There may be immediate repercussions for poaching via violence or other forms of aggression. There may be also a decrease in social standing, given one has breached social norms around exclusivity and relationships (see Sunderani et al. 2013, for discussion).

The poachers who are themselves currently in an existing, exclusive romantic relationship must deceive their partner. They may lie or manipulate their partner, keep themselves out of close proximity to the partner (e.g., "be away for work"), establish their independence (e.g., "I need space"), and perhaps increase their affection and resource allocation toward the current mate in an effort to avoid drawing suspicions of infidelity (Schmitt and Shackelford 2003).

It may also lead to the presence of future infidelity concerns and feeling uncertain about the future of the relationship. There are other costs, too, such as feeling guilty, issues around deception and lying, hiding the relationship, and potential rejection by one's family (Schmitt and Buss 2001). Individuals who then form a relationship with the poacher (or person poached) may experience feelings of jealousy, emotional pain, anxiety, and sadness; they may face serious risks due to these emotions such as intimate partner violence and homicide (see Sunderani et al. 2013, for discussion).

For men, there are also costs related to potentially depleting their resources while engaging in poaching behavior, especially if those resources could be used more productively to gain access to,

and retain mates. Men who lose their partner to a mate poacher face further costs, not only do they experience the loss of a mate (i.e., the poached individual) but also they risk losing any invested resources. Misallocated investments may also stem from the possibility of raising a child who is genetically unrelated, if their partner is poached, becomes pregnant, and then returns to the relationship.

Both sexes face the increased risk of illness; as one accesses new sexual partners, risks of sexually transmitted infections and diseases increase. There is also an increased probability of partner's future infidelity, if they were successfully poached in the past. Women face additional costs of potential unwanted pregnancy, as well as potential feelings of self-degradation, and concerns about future infidelity (Schmitt and Buss 2001).

Reasons to Poach a Mate

The reasons to poach a mate vary. Schmitt and Buss (2001) found several potential reasons, as follows. First, within a long-term context, men may be enticed by a woman's physical attractiveness while women may be enticed by a man with resources. Indeed, highly attractive women are more likely to be the targets of mate-poaching attempts and less likely to remain faithful in a relationship. Women do not show the same benefit of gaining an attractive mate via poaching although men who are targeted by poachers self-report they are physically attractive (Sunderani et al. 2013). Men also report a potential benefit of gaining access to a variety of sexual partners, as well as easy sexual access within short-term mate poaching contexts. Thus, sexual variety, attracting a beautiful partner, and freedom from responsibility for men are considered short-term benefits (Schmitt and Buss 2001).

Men do not consider receiving resources as beneficial as women do, or consider gaining a partner with the ability to accrue resources as beneficial. Interestingly, the benefit of receiving immediate resources was considered strongest in women considering short-term mate poaching, as opposed to long-term mate poaching. Women also

reported the additional reasons of taking revenge on a rival and gaining an already proven mate.

Personality of Mate Poachers and Those Who Are Poached

Schmitt and Buss (2001) examined various personality traits in relation to mate poaching. They found that agreeable and conscientious (i.e., care and think about other's feelings) people are significantly less likely to be poachers regardless of sex. Further, those who self-describe as having erotophilic dispositions more likely to have tried to poach. Individuals who reported success at poaching generally are more sexually attractive and lack sexual exclusivity. Extraverts and those open to experience receive more mate-poaching attempts, as do those who describe themselves as being emotionally investing in a relationship. Disagreeable, unconscientious, and neurotic individuals tended to accept mate poachers' advances, as did those describing themselves as mean, unreliable, adulterous, masculine, and unloving.

A lower level of conscientiousness is associated with increased sexual risk-taking, as well as perceived benefit of such behaviors. The lack of empathy linked to being unconscientious, higher disagreeableness, and disregard for others' well-being may empower individuals to poach a mate when faced with an opportunity and decrease their perception of any associated costs (Mitchell et al. 2019). Indeed, Foster et al. (2014) report that poachers tend to have more uninhibited sexual attitudes and behaviors. Poachers of both sexes self-report a higher number of lifetime sex partners, more lifetime casual sex partners, and more lifetime dating partners (Arnocky et al. 2013).

Sunderani et al. (2013) report that men who poach are better looking, taller, and have higher cortisol levels, which is a hormone that has been linked with impulsivity and extroversion. They also have higher self-esteem, which may lead them to believe they will be more successful at poaching and subsequently more likely to attempt to poach. They have higher criminal tendencies and more of a cold affect (i.e., little concern about others). They suggest that these characteristics

enable the individual to behave without feeling empathy or facing moral objections with respect to poaching. They also surprisingly found that men with lower levels of testosterone were more successful at mate poaching, which requires further study. In contrast, they found for women who poach, the only important factor is that they are attractive.

The dark triad of personality traits (DT) also matters. Kardum et al. (2015) reported that the DT predicts mate poaching experiences better than the Big Five traits, which are openness, conscientiousness, extraversion, agreeableness, and neuroticism. These authors report that the DT trait of psychopathy and the Big Five trait of extraversion are the most consistent predictors of mate poaching experiences. However, there are also noteworthy sex differences. The DT better predicts being the target of a poaching attempt in women and being successfully poached in men. Also, the Big Five traits better predict success at mate poaching for men.

The relationship between personality and mate poaching is small to moderate, according to Kardum et al. (2018). Poaching attempts, poaching success, and being the target of poaching appear to be more strongly related to personality than being successfully poached or being the victim of poaching. They further report that the link between mate poaching and personality are cross-cultural and similar in both short- and long-term relationships.

Targets of Mate Poaching

There are particular qualities of individuals who make them more susceptible targets for being poached. For example, tactics related to mate poaching are perceived to be more effective when the relationship where someone is being poached from is long-distance, not committed, about to end, or that is a dating relationship (Schmitt and Buss 2001). The specific role of the type of relationship within a mate poaching context depends on the tactic. Women are viewed as most effective when they use tactics related to emphasizing their physical appearance, while

men are seen as most effective when they emphasize their resources and generosity. In short-term contexts, women are perceived to be most effective when they advertise, provide, and arrange easy sexual access. Men who manipulated the emotional fidelity of the existing male partner were seen as effective at poaching, while women who manipulated the sexual fidelity of the existing female partner were also seen as effective (Schmitt and Buss 2001).

Individuals who are extraverted and high in openness (sensation seekers), sexy, adulterous, or high in neuroticism are typical targets also. There may be sex differences also. Moran and Wade (2019) report that men are most likely to attempt to poach from a couple where there is a discrepancy in the attractiveness of the members of the couple. Specifically, men are more likely to attempt to poach from a couple where the woman is more attractive than her partner, and men think that a poaching attempt towards this type of couple will be most successful. The duration of the relationship matters also. Moran et al. (2017) and Moran and Wade (2019) report that for short-term mating, men are more willing to poach women who are more attractive than the mates those women are involved with in a relationship.

Disguising Mate Poaching

Since mate poaching can have dire consequences for mate poachers if their behavior is detected, individuals may disguise their poaching attempts. Tooke and Camire (1991) point out that men in particular use a complex repertoire of deceptive tactics to gain access to reproductively viable women. Schmitt and Shackelford (2003) specifically examined tactics within the context of mate poaching, first within the context of how people signal an openness to being poached and then in terms of disguising their poaching.

In the first part, they asked students (11 men and 18 women) to nominate behaviors that they think people perform while already in a relationship to let others know they are open to another relationship. The participants were asked to consider behaviors one might do to advertise an

interest in short- and long-term relationships. Then, they asked students (26 men and 46 women) to rate the effectiveness of the behaviors in signaling interest in a new relationship. They found the most effective tactics for men seeking a short-term relationship were to enhance the potential mate (e.g., boost her ego, compliment her, tell her she deserves someone better), use humor, and be generous (e.g., show they are caring, polite, helps her with work or chores), while for women, it was arranging and providing easy sexual access, and enhancing the potential mate. For men, seeking a long-term relationship effective tactics were the same, while for women, it was to develop emotional closeness (confide in him, try to be a good friend, discuss mutual interests), mention they are looking for a replacement mate, and being generous.

In the second part, they again used an act nomination approach and asked students (20 men, 37 women) to list ways people disguise mate-poaching attempts for short- and long-term relationships. The poachers were stated to currently be in a relationship and who are attempting to disguise their actions in order to maintain that relationship. Then, another group of students (36 men and 44 women) rated the effectiveness of the tactics. The results indicated that the most effective ways to disguise mate-poaching attempts by men are as follows: talk with current partner about their future together as a family, pay closer attention to their current partner, keep constant watch on their current partner to see if they have suspicions, have deep emotional talks with their current partner, spend more quality time with the current partner, pretend one is happy with the current partner, spend less time away from the current partner, tell the current partner he is satisfied with their relationship, and do not discuss the new partner with anyone.

The researchers also examined what the most effective ways for women to disguise their poaching attempts are. Like men, many of these tactics are oriented toward their current romantic partner, such that they are attempting to maintain that relationship. The tactics are: maintain her daily routine to avoid causing suspicion, do not change her physical look, always return home at

same time each day, wear her relationship (e.g., wedding, engagement, promise) ring all the time, do not discuss the new partner with anyone, become more romantic with the current partner, attend fewer parties so as to be seen less, have sex more often with the current partner, rekindle the romance of the current relationship, and do not act like anything is different.

The authors also examined how many of these actions are also effective for men and women to keep their social community from knowing they are engaged in mate poaching (Schmitt and Shackelford 2003). However, while there is overlap in some tactics, there are also tactics that seem specifically oriented toward hiding information about the mate poaching from one's social community. For men, the most effective ways are as follows: do not discuss the new partner with anyone, keep a constant watch on the current partner, think before he speaks in public, have deep emotional talks with the current partner, spends less time away from the current partner, behave affectionately toward the current partner, talk with the current partner about their future together as a family, pretend he is happy with the current partner, and get the current partner pregnant.

A similar list was obtained for women; the most effective ways for women to disguise their poaching attempts are as follows: maintain her daily routine, do not change her physical look, always return home at same time each day, do not act like anything is different, keep her conversation routine and not talk about what is really going on in her life, never tell anyone about her new partner, keep the current partner sexually satisfied, wear her relationship ring all the time, behave affectionately toward the current partner, and rekindle the romance of the current relationship.

Schmitt and Shackelford (2003) concluded that overall, women are most effective at mate poaching when they advertised or provided sexual intimacy and discounted improvements in physical appearance. Women were seen to be most effective at disguising their mate poaching when maintaining daily routines. For men, the most effective tactics are when they advertised their resources and used tactics related to establishing an emotional connection. The best disguise for

men was when they talked to their current partner about their future together as a family.

Some of these findings have been recently replicated. For example, Moran and Wade (2017) performed a two-part study. In study 1, they asked heterosexual men to nominate acts they would use to mate poach someone specifically for a short-term relationship. In study 2, men and women reported which of those acts would be most effective. The most effective acts were spending time together, being attentive, being compassionate, helping her with her problems, and complimenting her. The authors propose these acts, when performed by men, signal altruism and emotional commitment, which women prefer in mates.

Relationships Outcomes

Despite the volume of research on mate poaching, there has been a dearth of investigation into the quality of relationships involving poached individuals. Two studies are worth noting, though, that address this issue.

Foster et al. (2014) examined the relationship quality of 138 heterosexual young adults over a 10-week period. They reported that poached individuals perceive potential relationship alternatives to be higher in quality and have more infidelity in their current relationship than non-poached individuals. Poached individuals are less committed to their current relationship and less satisfied overall, as compared to those who were not poached.

Belu and O'Sullivan (2018) extended this prior work by examining a variety of issues related to relationship quality in 675 heterosexual adults, which included a specifically solicited sample of those with mate poaching experience. They report individuals in romantic relationships formed by poaching rated their relationships as having lower satisfaction, commitment, and trust, higher jealousy, and higher rates of emotional and sexual infidelity compared to those in non-poached relationships (Belu and O'Sullivan 2018; largely replicating Foster et al. 2014). Further, those who were poached compared to those who did the poaching also rated their current relationship as lower in commitment (Belu and O'Sullivan

2018). The link between poaching and relationship quality is influenced by sociosexuality. Poachers tend to have more permissive and less restrictive views of sexual behavior, and require less commitment which is often the cornerstone of exclusive relationships. Thus, is it not surprising that mate poachers have an increased probability of engaging in an infidelity while in a relationship (Belu and O'Sullivan 2019).

Sexual Versus Emotional Mate Poaching

One area for future research may be to further investigate how mate poaching may occur in sexual versus emotional contexts. Research into infidelity has typically examined it in terms of whether the behaviors relate to sexual infidelity or emotional infidelity. Mitchell et al. (2019) extended this work by examining sexual versus emotional mate poaching. They report that mate poachers who engaged in sexual intimacy with their poached partner differed the most from those who did not poach their current partner on several dimensions, including higher antagonism, disinhibition, risk-taking, and lower humility and honesty. They further documented that men who engaged in sexual intimacy with their poached partner reported higher levels of detachment, antagonism, disinhibition, psychopathy, and lower levels of conscientiousness, humility, and honesty. The authors suggest that this combination of traits may allow a mate poacher to maintain a physical relationship with an already partnered individual because it includes a willingness to deceive and manipulate others for personal gain, and the discounting of potential costs.

For comparison, men who engaged in emotional mate poaching still reported high levels of antagonism, disinhibition, and ethical risk-taking, and lower scores for humility and honesty than non-poachers. However, their scores were lower for ethical risk-taking than men who engaged in physical mate poaching. The researchers propose that the differences between the two poaching groups may be due to seeking alternative paths to poaching. That is, men who engage in emotional mate poaching may be attempting to establish a romantic bond with trust rather than sexual

access. Women, for comparison, did not demonstrate as many differences between the two forms of poaching as men, and most of the traits were not exhibited as strongly as men.

Conclusions

In this entry, we briefly reviewed the extensive literature on mate poaching. Our review started with issues surrounding differences in definitions of the behavior, and how it is distinct from other forms of romantic attraction. We then discuss prevalence, showing that there is cross-cultural variation in mate poaching, but also differences according to an individual's sex and according to whether one examines any poaching experiences or frequent experiences. The considerable costs associated with mate poaching were reviewed, followed by a discussion about the potential benefits one may receive. We then shifted our focus to present an overview of some of the findings about personality of those involved in mate poaching relationships, as well as characteristics of targeted individuals. Research on how mate poaching may be disguised was reviewed, along with details about some of the tactics men and women are thought to use. We presented the small body of research on the outcomes of relationships that started with one individual being poached. We then ended our review with an example of an area for future research, which is the examination of mate poaching along sexual versus emotional lines, akin to the large corpus of work on infidelity. Collectively, our review demonstrates the variety of ways mate poaching has been explored using the lens of evolutionary psychology and how the topic has changed in scope over time.

Desires in mating; Mate choice; Mate selection

Definition

Mate preferences are the outputs of psychological mechanisms designed to motivate people to

pursue potential mates who possess particular qualities. Preferred features range widely. They include morphological (e.g., face or body shape), behavioral (e.g., kindness or dominance), or social (e.g., status or connections) attributes. Mate preferences can be species typical, sex differentiated, individually variable within sex, culturally variable, and predictably context dependent.

Introduction

Human mate choice is not random. Given the choice between a kind healthy partner and a disease-afflicted cruel partner, most people would prefer the first over the second. These preferences determine who we are attracted to, who we pine for during absences, and who we write books, plays, songs, poems, and films about. They affect who we select as mates; who we live with, support, and receive support from; and, for some, with whom we raise children. They influence who has experienced mating successes and failures in our evolutionary past, which is key to which qualities increase or decrease in frequency over time. Given this monumental importance, it is appropriate that mate preferences have been one key cornerstone of evolutionary psychological research. This research uses an understanding of what preferences are *for*, that is, their evolved functions, to understand what human preferences are *like*, that is, their content and nature. The study of mate preferences has thus far been extraordinarily successful, generating a large body of knowledge on the content of human desire across cultures and across contexts.

Why Do Mate Preferences Evolve?

Understanding mate preferences first requires an understanding of why they evolve. Humans are a sexually reproducing, social species who bear offspring who are initially helpless and dependent on parental investment for nearly two decades. For our species, a mate is thus a reproduction partner, a potentially valuable cooperation partner, a source of social connections, a parenting

partner, and more. Who an ancestral human selected as a mate would have had direct impacts on that person's health, their resources, their status, the parenting their children received, the traits their children inherited, and, ultimately, through these many routes, their reproductive success. Selection would have strongly favored the evolution of adaptations capable of guiding their holders toward fitness-beneficial partners because individuals with these adaptations would have greatly outcompeted their reproductive rivals.

The challenge for sexually reproducing organisms in mate selection is that they have no way, *a priori*, to determine which mates offer fitness benefits and which mates inflict fitness costs. Potential mates vary on innumerable trait and state dimensions. Some mates are larger than others; some have longer limbs. Some control more resources; others command more status. Some mates are kinder than others; some are more outgoing. Some mates have a larger ratio of dirt on their upper body relative to their lower body. Some have a higher or lower speed of fingernail growth. Only a miniscule subset of the infinitely many dimensions along which potential mates differ would actually be relevant to the net fitness benefits a potential mate offers.

Even if an organism could, against astronomical odds, guess which dimensions of variation should be relevant to its mate selection, it would have no means to know the valence the dimensions should be assigned. Is it better to have a large mate or a small mate? Do older mates offer more fitness benefits than younger mates? Does a healthy mate offer more fitness benefits than a wealthy mate? The answers to these questions will depend on species, sex, mating strategy, and context. A naïve organism could search the environment for its entire lifetime and still never determine the correct valence to assign to even one dimension along which potential mates vary.

So sexually reproducing organisms face a critical adaptive problem in selecting mates who offer them the largest net fitness benefits. Solving this problem appears to be computationally intractable. Each organism has an infinite number of dimensions of variation along which it could evaluate potential mates and an infinite number of

valences it could assign to each dimension. How, then, do organisms ever solve the adaptive problem of selecting fitness-beneficial mates?

One potential solution to the problem of mate choice is mate preferences. Although organisms may never *know* what dimensions of variation it should use to guide its mate selection, random mutations will eventually cause some organisms to have motivational biases in favor of pursuing mates with particular features. Most of these random preferences will motivate organisms to discriminate among potential mates along inconsequential dimensions or with nonfunctional valences. But a very small proportion of these mutations will cause organisms to be motivated to pursue mates who possess fitness-beneficial features or to avoid mates with fitness-harmful features. Those individuals who happen to develop functional mate preferences will be attracted to beneficial mates and, over deep time, will be more likely to select adaptive mates and experience reproductive success. In this way, genes underlying preferences for fitness-beneficial features will tend to reproduce themselves over time, causing sexually reproducing organisms to accumulate mate preferences for fitness-beneficial features.

How Do Mate Preferences Evolve?

The evolution of mate preference adaptations will be favored by selection to the extent that these preferences guide organisms to fitness-beneficial partners. There are at least two routes through which preferences could provide fitness benefits: direct benefits delivered to the mate selector and indirect benefits delivered to the mate selector's kin.

Direct benefits delivered to the mate selector. The most obvious and likely most frequent route to the evolution of mate preferences is through the receipt of direct benefits. Preferences offer direct fitness benefits when they guide organisms to mates who offer fitness benefits directly to the mate selector. A classic example is nuptial gifting in insects. Female katydids prefer to mate with males who offer them

“spermatophores”: packages of food which the females consume during mating. These spermatophores are extremely energetically dense and provide females the energy they need to survive and reproduce. Because these spermatophores meet all of the females' energetic needs, females who are provisioned can focus their time and energy on reproduction rather than foraging. The preference for males who provide spermatophores therefore provides katydid females a direct fitness benefit by allowing them to increase their own rate of reproduction.

Nuptial gifts concern the explicit exchange of benefits between mates; however, direct benefits can also come from less tangible sources. For example, males of many reptile species prefer to mate with larger females (e.g., Shine et al. 2001). These preferences appear to evolve because larger females are generally able to produce more eggs. Males who prefer to mate with larger females consequently receive a direct fitness benefit in that they can produce more offspring with their mates.

What is key about direct fitness benefits is that they increase the reproduction of the mate selector. These fitness benefits can be in the form of mates who offer resources or offspring provisioning that allow the mate selector to direct extra time and energy to reproduction. Benefits can come from access to prime territories or social groups that provide shelter or resources. Or they can come from access to fertile partners with whom the mate selector can produce many offspring. Securing any of these features in a potential mate will allow the holder of a mate preference to produce more offspring and thereby better reproduce the genes underlying their preferences.

Indirect benefits delivered to the mate selector's kin. The benefits of mate preferences need not go directly to the mate selector; fitness benefits can also flow indirectly by benefitting the kin of the mate selector. Selection can, for instance, favor the evolution of preferences for heritable features of potential mates if these preferences lead to offspring who are healthier, more fertile, or more successful in acquiring mates. One commonly hypothesized preference for this class of benefits across species involves the preference for

symmetry (Møller and Pomiankowski 1993). Many species are, by design, bilaterally symmetric: morphological traits on the left half of the body are supposed to be mirror copies of traits on the right half. Although this is the norm at the species level, few if any individuals are ever perfectly symmetrical. Individuals will tend to show random asymmetries throughout their bodies. Among birds, for example, although wings are of equal length on average, most individuals will have one wing that is slightly longer than the other (Møller and Pomiankowski 1993). These asymmetries are typically slight, but can occasionally be large.

Asymmetries are thought to reflect the stability of individuals' development. Because organisms are supposed to be symmetric, asymmetries provide a documentation of developmental "errors": instances where the individual's body failed to organize itself according to design. The developmental errors that cause asymmetries can also cause issues with survivability and health across several species. Further, these errors can result from environmental stresses but can also emerge because of genetic mutations. Symmetry therefore can signal direct benefits, but can also provide indirect benefits: individuals who select symmetric mates are selecting mates with heritable genetic endowments that on average produce healthier, more survivable offspring.

Any feature of a potential mate that provides reproductive benefits to offspring provides, through inclusive fitness, an indirect fitness benefit to the mate selector. This can include heritable features that increase health, fertility, or competitiveness on the mating market; but, particularly in cultural species, indirect benefits can also come from transmissible features such as wealth, status, or knowledge. By selecting mates who can benefit one's offspring, an individual with mate preferences that yield indirect benefits will produce offspring who are more likely to survive and reproduce and thereby reproduce the genes underlying their mate preferences.

Sensory exploitation. Many mate preferences across species appear to be functional, but preferences can also evolve as byproducts of other adaptations. One common evolutionary route to

by-product preferences occurs when perceptual adaptations evolved for other processes are hijacked by potential mates to gain attraction in the mating domain. This process is called "sensory exploitation" and appears to have created mate preferences across several species. Tungara frogs provide the prototypical case of sensory exploitation. Females of this species prefer to mate with males who produce a distinctive chuck sound. However, this preference does not appear to be functional. Rather, female tungara frogs have evolved a species detection system which contains an auditory bias toward sound frequencies produced by tungara frog males but not by males of other frog species. After females evolved this sensory bias, tungara frog males evolved the chuck: a meaningless sound which happens to maximally stimulate females' species detection system (Ryan et al. 1990). Female tungara frogs consequently show a mate preference for chucks that evolved purely as a by-product of a species detection adaptation.

Any perceptual adaptation that can motivate approach or avoidance can in principle be exploited by potential mates to manipulate attraction in the mating domain. The exploitation of existing perceptual adaptations is therefore a potentially common route to the evolution of mate preferences. The result in any case of sensory exploitation is potential for a coevolutionary arms race. Individuals of one sex will evolve adaptations that allow them to better exploit their potential mates; in response, individuals of the opposite sex will evolve sensory defenses to the extent that being exploited is costly. These escalating arms races will craft adaptations that shape how organisms perceive and interact with their worlds as well as shape their mating systems and mating behaviors. Understanding when and how perceptual adaptations are exploited in the mating domain can thus provide researchers insight into the nature of species' perception and mating.

Outstanding theoretical issues in the evolution of preferences. Evolutionary biologists have made considerable progress in developing theory concerning the evolution of mate preferences. But some areas of mate preference theory remain unclear or underdeveloped. One centers on the

distinction between direct benefits to the mate selector and indirect benefits through benefits to kin. These sources of benefits are often considered categorically distinct, but it must be stressed that they can overlap. For instance, a preference for mates willing and able to invest resources in offspring could provide direct benefits to the mate selector by providing supplemental parental investment but also indirect benefits if this provisioning increases offspring reproduction beyond what single parental investment would alone. A preference for good immune functioning could provide indirect benefits by producing healthier offspring but also direct benefits in lowering the risk of being infected by partners. When considering the functions of mate preferences, researchers must take care to consider the many and potentially overlapping functions of preference adaptations.

Indirect benefit hypotheses further focus largely on genetic benefits to direct offspring. But there are many potential ways by which preferences could provide indirect benefits to kin. First, the kin receiving benefits need not be direct offspring. A gene for a mate preference could increase its own reproduction if it were able to provide fitness benefits to siblings or other genetic relatives. A mate whose status or resources are able to spill over and increase the reproduction of siblings can produce fitness benefits by increasing the reproduction of preference genes they probabilistically share with the mate selector. Mate preference researchers must consider the many potential targets of indirect benefits when hypothesizing evolved functions of mate preferences.

What Do We Know About Human Mate Preferences?

Ample theory and evidence documents the ways in which evolution has shaped mate preferences in nonhuman species. Do human mate preferences show the same evolutionary fingerprints? Mate preference research has been a cornerstone of evolutionary psychology since the field's inception (e.g., Buss 1989). This research has discovered an impressive and growing catalog of human preferences evolved to serve a variety of functions.

Direct benefits. Humans across cultures hold mate preferences hypothesized to have offered direct fitness benefits to human ancestors. One well-studied example concerns preferences for resources in potential mates. Human offspring are enormously costly, and they demand relatively large investments of resources to raise successfully. This is particularly true for women, who alone face the substantial energetic, temporal, and opportunity costs of pregnancy and up to several years of lactation. Analogous to female katydids, ancestral women could have partially offset these large reproductive costs by preferentially mating with partners who were willing and able to share resources with them.

Modern women across cultures consequently express a preference for potential mates who control resources that can be invested in them and their families. Buss (1989) surveyed 10,047 men and women across 37 cultures for their mate preferences in an ideal, long-term relationship partner. These cultures varied widely in religion, climate, and economic, political, and marriage systems. Yet despite this incredible diversity, in every culture, women, more than men, expressed a strong preference for potential mates who possess economic resources. This preference is not limited to modern cultures: women among the Hadza hunter-gatherers express a preference for men who are good hunters and therefore good providers of essential resources (Marlowe 2004).

Direct benefit preferences are not limited to women. One critical adaptive problem ancestral men would have faced in the mating domain is identifying mates who are fertile. Men who were able to target their mating effort toward women who were particularly fertile would produce more offspring than men attracted to less fertile women. However, women are fertile during only a relatively narrow period of their lives – after puberty and before menopause. Further, unlike many other mammal species, human ovulation is relatively concealed: whereas chimpanzees develop prominent genital swellings around ovulation, human women show only small changes around the fertile period of the menstrual cycle.

How could ancestral men identify and select fertile partners, since fertility, unlike estrus, is not

directly observable? Men's mate preferences appear to have solved this adaptive problem by drawing men to women who show cues statistically correlated with their fertility. Attributes of physical appearance and behavior provide a wealth of potential cues. One is a woman's body shape and particularly waist-to-hip ratio. Relatively low ratios of waist circumference to hip circumference are associated with young age, non-pregnancy status, fewer diseases, and an easier time getting pregnant. A low WHR is found attractive by men across cultures (Sugiyama 2005). Men's mate preferences also guide them toward mates with beneficial hormone profiles. Higher levels of ovarian hormones, including estradiol, are associated with a higher likelihood of conception (Lipson and Ellison 1996). Facial femininity is strongly correlated with estradiol levels in women; men are also strongly attracted to women who are facially feminine (Smith et al. 2006). This hormone-attractiveness link emerges in facial attraction, but also holds and emerges for body attraction: controlling for BMI, higher levels of estradiol are associated with higher levels of bodily attractiveness (Grillot et al. 2014). Through various probabilistic cues, men's mate preferences are able to guide them to mates who are relatively fertile.

Finally, one particularly important mate preference appears to capture direct benefits related to both resources and fecundity: preferences for the age of potential mates. Age is a key cue to both fecundity – the capacity to produce offspring – and resource acquisition. First, women are not fecund prior to puberty. After puberty, fecundity peaks roughly in the late twenties and early thirties and then gradually declines until menopause. A woman's age is thus a rough cue to her fecundity. Age is also a cue to reproductive value: roughly, the number of future offspring a person can be expected to have. Reproductive value typically peaks in the late teens and early twenties and declines thereafter. By seeking younger partners, ancestral men would have increased their odds of finding fertile reproduction partners. Age is additionally a useful cue to resource-earning potential. In both modern and traditional societies, men accrue more resources when they are older

than when they are younger. By seeking older partners, ancestral women could thus have increased their odds of securing partners with resources available to invest.

People accordingly show strong preferences for the age of their potential mates. Across cultures, men express a desire for younger partners whereas women express a desire for older partners (Buss 1989). This trend has held across decades in India, China, and Brazil (see, e.g., Souza et al. 2016). These preferences manifest not only in what people say but also in what they do: for example, marriage records across cultures show that husbands tend to be older than their wives (Kenrick and Keefe 1992). This difference appears in marriage records extending as far back as the nineteenth century in Swedish records (Low 1991).

Indirect benefits. Providing evidence for preferences evolved through indirect benefits is more difficult than providing evidence for preferences evolved via direct benefits. Nonetheless, humans have some mate preferences that are hypothesized to have evolved because they supplied ancestral humans with indirect fitness benefits. One concerns symmetry: human bodies are bilaterally symmetric by design, but all people show some degree of asymmetry. And just as in other bilaterally symmetric species, humans show a preference for symmetry in potential mates. More symmetric faces are found to be more attractive in both experimentally manipulated and natural faces (e.g., Scheib et al. 1999).

Another prominent preference hypothesized to have evolved via indirect benefits is women's preference for masculinity. Masculine facial, bodily, and behavioral attributes are thought to signal exposure to testosterone. Testosterone plays an important role in energy allocation: testosterone causes bodily systems to shift energy toward the development of muscle and away from maintenance processes such as immune functioning (Simmons and Roney 2009). Therefore, it is thought that only men who have “good genes” – that is, those for robust immune systems – can afford to produce large amounts of testosterone and develop highly masculine features. Consistent with this hypothesis, facial

masculinity and asymmetry are correlated in men, suggesting they tap an underlying dimension of genetic quality (Gangestad and Thornhill 2003). By mating with masculine men, women with a preference for masculinity would bear offspring who inherit their good genes and thereby good immune systems. Evidence for attraction to masculinity is mixed, but women do appear to be more attracted to masculine men in short-term, sexual contexts (e.g., Little et al. 2002).

Despite longstanding research focus on preferences for masculinity, two complications exist for the indirect benefit hypothesis: one methodological and one theoretical. First, evidence is mixed that masculine features reflect circulating testosterone levels as opposed to early life exposure to testosterone (e.g., Whitehouse et al. 2015). If masculine facial features do not reflect circulating testosterone levels, then they do not clearly signal the ability to bear the costs associated with producing large amounts of testosterone. Second, even if masculinity were clearly related to attractiveness and circulating testosterone, these findings would not, on their own, suggest that preferences for masculinity evolved because they provided indirect benefits to human ancestors. An alternative possibility is that preferences for masculinity function to guide humans to healthy partners. These partners would have provided human ancestors direct benefits both in being less infectious and in being more likely to survive to co-parent mutual offspring.

Contextual shifts in preferences. Historically, at least some traits would have offered variable fitness benefits across contexts. Selection should have favored the evolution of mate preference adaptations that are sensitive to these contextual shifts in fitness benefits. Preference mechanisms should take information about the current state of the environment as input and moderate the strength and nature of preferences in response. One context variable studied in the extant literature is pathogen exposure. Pathogens are more prevalent and pose a greater threat under some conditions and in some environments (e.g., warmer climates). Under such contexts, preferences for health in potential mates would have historically provided greater fitness benefits and

so selection would have favored the evolution of preference mechanisms sensitive to pathogen prevalence.

Preferences for physical attractiveness in potential mates appear to be one such context-sensitive preference (Gangestad and Buss 1993). Several studies suggest that physical attractiveness is at least a moderate cue to health (Sugiyama 2005): people who are more physically attractive tend to be healthier across a wide array of indices. Ancestral humans who more heavily prioritized physical attractiveness under conditions of high pathogen threat would therefore have been more likely to select partners who were able to survive disease threats and remain healthy. Additionally, to the extent that immune functioning is heritable, these people would be more likely to produce offspring with strong-enough immune systems to survive in their local, high-pathogen threat environments. Accordingly, modern humans living in ecologies with greater pathogens report stronger preferences for physical attractiveness in potential mates (Gangestad and Buss 1993). Women's preference for masculinity in potential partners specifically varies across cultures related to the health of those cultures: in countries with greater health risks, such as pathogen threat, women express stronger preferences for masculinity in potential mates (DeBruine et al. 2010).

Mate preferences differ across environments, but they also shift within people across contexts. For instance, the traits that are beneficial in a potential mate depend on the mating strategy one is pursuing. For men, a key benefit of short-term, uncommitted mating is access to multiple sexual partners (Buss and Schmitt 1993). This access would be hampered by mate preferences that set high standards for potential mates. Men's mate preferences consequently shift as a function of their mating strategy. When men are pursuing a long-term, high-commitment mating strategy, their preferences set high standards for the intelligence and kindness of their potential mates (Kenrick et al. 1990). When men are pursuing uncommitted, short-term partners, they substantially lower their preferences for kindness and intelligence, which presumably allows them to

mate with a variety of short-term partners. Importantly, men's physical attractiveness preferences remain relatively strong across mating strategies: healthy and fertile partners are always beneficial to men, and so preferences for these traits are relatively insensitive to mating context.

Women's mate preferences also shift across context. One well-studied contextual shift concerns shifts in women's mate preferences as a function of ovulatory status. A growing body of literature suggests that when women are ovulating, they more strongly prefer potential mates who are symmetric, with masculine bodies, and show dominant behavioral displays (Gildersleeve et al. 2014). These preference shifts are generally stronger when women are considering short-term, sexual partners rather than long-term, committed, romantic partners. Because women can only conceive offspring when or just before they are ovulating, these preference shifts have been hypothesized to function in motivating women to conceive offspring with partners who possess "good genes" – including those that allow them to build and maintain symmetric and masculine phenotypes. However, although many of these ovulatory shift effects appear to be empirically robust, the ultimate function of these shifts remains heavily debated. Alternative theoretical accounts include proposals that preference shifts are byproducts of adaptations calibrated to between-women differences in fertility and byproducts of adaptations designed to calibrate preferences to differences in fertility within women between menstrual cycles (see, e.g., Roney 2009).

What Is Not Known About Mate Preferences?

Despite the considerable and growing body of knowledge, many uncertainties remain about the nature of human mate preferences. These questions span the levels of Tinbergen's four questions and include issues of the development, mechanism, and function of human preferences.

Development. Mate preference research has focused largely on the content of adult mate

preferences. Almost no research explores how preferences develop into these mature forms. This developmental question encompasses several sub-questions. For instance, when, developmentally, do mate preferences come online? Because mate preferences presumably function to guide mate selection, one intuitive hypothesis is that mate preferences will not generally emerge until humans begin their mating careers – that is, at puberty. However, some evidence indicates that at least preferences for physical attractiveness appear very early in life (e.g., Langlois et al. 1987). Different preference adaptations may activate and deactivate at different points across the lifespan depending on when they would have been most functional throughout human evolutionary history. The developmental emergence of mate preferences is a very open and important area of inquiry.

A second question concerns the factors that affect the developmental trajectories of mate preferences. For example, mate preferences are known to vary somewhat across cultures (Buss 1989; Gangestad and Buss 1993). These cultural differences could be caused by psychological adaptations that actively calibrate mate preferences to local environments throughout the lifespan. However, an alternative developmental trajectory is that mate preferences are fixed relatively early on in life by environmental cues experienced in infancy or childhood. This relates to a third question: to what extent are mate preference adaptations sensitive to sociocultural cues? That is, do people have adaptations designed to promote learning of mate preferences from their cultures or social groups? Humans are known to engage in some degree of "mate copying": a learning process that appears across species wherein individuals learn to be attracted to potential mates based on the mate choices of others (Waynforth 2007). However, precisely what preference adaptations include these learning features, how long these learned changes last, and just how much learning can adjust the magnitude of mate preferences are still unknown.

Finally, relatively little is known about the developmental course of mate preferences across the lifespan. Many adaptive problems faced in

mate choice would have been age linked throughout human evolution. For example, women's fertility wanes at menopause. After this point, features of potential mates related to heritable benefits, such as the possession of good genes, could no longer provide fitness benefits. Accordingly, women's mating strategies appear to shift around menopause (Easton et al. 2010). These shifts are hypothesized to function in motivating women to take advantage of their fertile years. However, this is just one preference shifting at one point in women's lifespan. Little is known about the extent to which other preferences, such as those for resources, health, or fertility, change across the lifespan.

Mechanism. A central assumption of mate preference research is that mate preferences motivate people to pursue and select mates who fulfill those preferences. But preference researchers do not as yet understand how mate preferences are integrated to make actual mating decisions. Given preferences for mates who are, for example, intelligent, kind, and physically attractive and an array of potential mates who vary randomly on each of these dimensions, how exactly do people determine which mates are worth pursuing and which are worth passing over? How do we weigh a mate who is kind, attractive, and dull against a mate who is beautiful, smart, and rude?

Human mate choice psychology must have some psychological machinery that integrates our many mate preferences into summary decision variables, such as valuable as a mate or not. Several algorithms have been proposed for how this integration is accomplished. These include linear combinations similar to linear regression (Buss and Schmitt 1993), aspiration models involving series of thresholds (Miller and Todd 1998), nonlinear models involving trade-offs between necessities and luxuries (Li et al. 2002), and a Euclidean algorithm that minimizes the distance between desires and potential mates across multiple dimensions (Conroy-Beam and Buss 2016). Understanding the nature of human preference integration will be key to understanding both the content of human mate preferences and the downstream effects of these preferences on mating outcomes.

Function. Finally, mate preference research has been predominantly driven by functional hypotheses that propose mate preferences evolved to solve adaptive problems faced throughout human evolution. However, it is unlikely that all human preferences are the functional outputs of adaptations. At least some preferences are likely to be byproducts of other adaptations. For instance, the most common explanation for why humans prefer symmetry is that symmetry cues health and good genes (Grammer and Thornhill 1994). But it has also been proposed that symmetry preferences can emerge as byproducts of perceptual adaptations designed merely to detect, but not evaluate, mates who happen to be imperfectly bilaterally symmetric (Johnstone 1994). These hypotheses are not mutually exclusive: both functional and by-product preferences for symmetry could act to guide people toward symmetric partners.

Despite an apparent frequency of sensory exploitation in nonhuman animals (e.g., Ryan et al. 1990), sensory exploitation hypotheses for the evolution of mate preferences have not been explicitly explored in human mating. Many preferences whose functions are unclear – for instance, for attributes such as hair color and styling, dressing, dancing abilities, and so on – could exist because they hijack preexisting features of human perception. Exploring these sensory exploitation hypotheses has potential to provide psychologists insight into human perception and human mating.

The number and role of nonfunctional mate preferences remains an open empirical question. Full understanding of the breadth of human mate preferences will require preference researchers to explore by-product hypotheses alongside functional hypotheses as well as conduct empirical tests that compete by-product and functional hypotheses against one another for the ultimate origins of human mate preferences.

Conclusion

Mate preferences have pervasive effects on human life and human evolution. Mating is

central to differential reproduction, the engine of evolution by selection. All living humans are descendants of a long and unbroken chain of ancestors, each of whom successfully mated. Consequently, the study of human preferences has been a large part of evolutionary psychology since the field's inception. This research program begins with an understanding of how preferences evolve, including the receipt of direct and indirect benefits as well as by-product processes such as sensory exploitation. The application of these evolutionary theories has yielded a substantial body of evidence about the content of human preferences. This includes cross-cultural, sex-differentiated preferences for features such as possession of resources, future resource potential, symmetry, masculinity, and many cues to fertility, such as youth, femininity, and low waist-to-hip ratios. Preference research has also uncovered context sensitivity of many preferences, responsive to diverse circumstances such as personal mate value, pathogen prevalence, and mating strategy. Despite this large and growing body of knowledge, many questions remain open about mate preferences for future research. Preference researchers still have little understanding of how mate preferences develop over the lifespan, how multiple preferences are integrated with one another to make decisions about actual mate choice, and how some preferences might have evolved through nonfunctional routes such as sensory exploitation. Mate preference research is a large, successful, and vibrant research area with a long future ahead. The success of preference research contributes understanding of a large and critical domain of human life and underscores the value of applying an evolutionary perspective for understanding human psychology.

Definition

This section covers the theoretical considerations and existing data relevant to studying mate preferences after having children.

Introduction

Children dominate their parents' time and energy and siphon a significant portion of their accrued resources. Although having children changes people's lives substantially, the extent to which people's mate preferences change after having children is unclear. The current chapter

will address theoretical considerations important to developing hypotheses about mate preferences after having children and will summarize existing relevant data. First, because provisioning and caring for children was a recurrent adaptive problem, human mating psychology may have evolved to calibrate mate preferences to motivate the pursuit of partners who are able and willing to contribute resources and parenting effort and who will not pose a threat to existing children. Any shifts in preferences should be particularly pronounced in females who bear the brunt of obligatory investment costs. However, children also indirectly influence mate preferences because their presence alters parental mate value. Because children have a more detrimental effect on maternal mate value, we should again expect sex-differentiated effects on mate preferences. Finally, it is important to note that extended periods of childlessness in adulthood are a unique feature of modern, WEIRD (Western, Educated, Industrialized, Rich, and Democratic) populations. Observed mate preferences in childless adults may in fact be the product of mechanisms that evolved to guide mate selection of ancestral humans who already had children. Rationale for hypotheses that distinguish pre-children mate preferences from post-children mate preferences must offer evidence that mating mechanisms were shaped in an environment in which this difference was a recurrent selection pressure. Studies must disentangle differences in mate preferences after children from differences caused by potential confounding variables, such as mate value, status, or age.

Women's Preferences after Children

Women's mate preferences are influenced by a variety of contexts, including mate value (Buss and Shackelford 2008), ovulatory phase, and age. Mate preferences research highlights how women's obligate investment in offspring has acted as a recurrent selection pressure, shaping mating mechanisms. However, less research has addressed how sensitive these mating mechanisms are to the presence of current offspring. If

a woman is engaging in a mate search after already having children, she faces not only the adaptive problem of finding a partner who will invest in and help raise future shared offspring but also the adaptive problem of selecting a partner who will contribute towards her current children. This suggests two characteristics that women with children should particularly desire in potential mates: (1) partners who currently have resources to funnel to her and her offspring and (2) partners who are kind and nurturing toward her children and who do not pose a threat to them.

Children impose a particular resource burden on mothers, who are obligated to incur the energetic and resource costs of 9-months of gestation and, ancestrally, years of requisite breastfeeding (Marlowe 2005). As predicted by Parental Investment Theory (Trivers 1972), this difference in obligatory investment has shaped sex differences in human mate preferences. Across dozens of cultures, females place a greater premium on romantic partners' current and future ability to contribute resources than do males (Buss 1989). Existing children are an immediate resource burden. Unmated mothers, or mated mothers looking to mate-switch, should place an even greater importance on a potential mate's *current* ability to provide resources. This may manifest as an increased preference for cues to existing resources or an increased preference for cues to status, status-striving, ambition, and work ethic.

This hypothesis is supported by existing data. In one longitudinal study, the partnering decisions of over 2000 mothers drawn from a sample representative of the United States were assessed 5 years after their child's birth. About half of the mothers no longer with their child's father remained un-partnered. Of those who re-partnered, 60 % did so with a mate of higher economic potential than their child's father, 20 % with a mate of equal economic potential as their child's father, and 20 % with a mate of lesser economic potential than their child's father (Bzostek et al. 2012). This suggests that when women have children they become even more discerning about a mate's ability to contribute resources and may choose to remain unmated if they are unable to find or attract a mate meeting their heightened standards.

Even if a new partner has resources, he may be unwilling to funnel them towards children that are not his. Studies examining step-father monetary investment in children's college education in the United States, step-father monetary and time investment in high school-aged children in South Africa, and step-father time and care investment in children in the Hadza in Tanzania all demonstrate that step-fathers invest less in step-children than genetic children (Anderson 2005; Anderson et al. 1999a, b; Marlowe 1999). Mothers face a daunting task of selecting a mate who can and *will* help provision and care for her existing offspring.

Mothers also face the adaptive problem of selecting a mate that will not pose a threat to, or abuse, her existing children. A mother's new partner gains no direct reproductive benefit from investing in her children and may benefit from encouraging the mother to neglect and inflict costs on her current children to facilitate her investment in him and his children. The presence of a step-parent in the household vastly increases child abuse rates – in one study children living with a step-parent and a genetic parent were 40 times more likely to be abused than children living with both genetic parents (Daly and Wilson 1988). Step-parents are also more likely than genetic parents to kill children, and step-fathers in particular have the greatest tendency to kill step-children (Daly and Wilson 1988, 1994). Mothers would benefit by preferring new mates who display cues to kindness, interest in children, less aggression, and other indicators that they will not pose a threat to children. Women evidence such preferences even prior to motherhood (Buss 1989; Brase 2006). Cobey et al. (2015) found that women's preference for male facial masculinity decreased post-partum compared to their preference during pregnancy. This demonstrates a shift in preferences in mothers toward indicators that a potential mate will not threaten her child's survival. Women without children may be in the position to reap the benefits of mating with more masculine, less pro-social males because of the other benefits they provide. Mothers, on the other hand, may trade-off those benefits to ensure selecting a partner who will not harm her children.

The Effect of Children on Women's Mate Value

Although women would benefit from these shifts in preferences, their mating options and mating decisions will be limited by the effect children have on mate value. In other primate species, males are attracted to parous, older females, possibly because it signals mothering experience which would enhance infant survival or because it signals high genetic quality (Muller et al. 2006). However, humans are unique in that we form long-term pair bonds where males invest heavily in offspring. This has shaped men's preferences for younger women with high reproductive value from which they can maximally benefit. Children may provide a cue to more advanced age and fewer remaining reproductive resources, decreasing women's attractiveness. Although there is evidence that women who do not stay with their child's father are more likely to re-partner with a mate with better economic potential, unmarried mothers tend to mate with less educated men with fewer resources than their childless counterparts (Graefe and Lichter 2007; Lichter and Qian 2008). Men are less likely than women to report being willing to marry someone with a child (Goldscheider and Kaufman 2006). If children reduce a woman's mate value, making it more difficult for her to attract high quality mates, she may be forced to make tradeoffs in her mating decisions. A woman's attractiveness is positively correlated with preferences for a variety of characteristics in a mate, including emotional stability, education, potential income, and physical attractiveness (Buss and Shackelford 2008). Women high in mate value can attract the most sought after mates who embody all of women's preferences. Women with children cannot be highly selective in general but need to be specifically selective to ensure the provisioning and protection of their existing children.

Future studies examining women's mate preferences after having children must account for these competing selection pressures. We may see greater variability in the importance placed on different mate preferences in women with children compared to nulliparous women. Mothers

may place high premiums on characteristics like current resource holdings, willingness to invest in children, and prosociality but be willing to sacrifice other characteristics, like physical attractiveness and dominance, particularly because of their lower mate value. Non-mothers may maintain higher standards across female-typical mate preferences, in hopes of attracting a mate with the best combination of traits.

Men's Mate Preferences after Children

Historical and cross-cultural data shows that men engage in parental care less intensively than women (Geary 2000). As such, we should expect existing children to have less of an effect on men's mate preferences than women's. Any effects may depend largely on the amount of investment a father devotes to his children. Furthermore, children may have the opposite effect on father's mate value than mothers. Observing a father investing in current offspring provides a singular cue to interested females of his parenting abilities, possibly increasing his mate value (Brase 2006). Investigations into how children influence mate preferences need sex-specific rationale that will generate sex-differentiated hypotheses.

Although women bear the greater obligatory investment costs and often invest more in offspring, human males are unique among primates in that they provide high levels of parental care. This care influences their children's survivability and well-being. Having divorced parents predicts higher mortality rates in various countries, including Indonesia, Sweden, Germany, and the United States (Geary 2000). In a study of the Ache in Paraguay, father absence before the child turns 15 is associated with a mortality rate of 45 % compared to a 20 % mortality rate in children with present fathers (Hill and Hurtado 1996). Father's investment also predicts children's ability to compete for social and material resources, educational attainment, and physical well-being (Geary 2000). There is large variability among males in energy devoted to parenting effort – while some display high levels of investment, others invest little in offspring, instead devoting

those resources and energy towards obtaining additional mating opportunities. This is a key variable that should predict whether or not children have an influence on men's mate preferences.

Men who invest highly in offspring, devoting a large amount of their time and resources to their children may experience mate preferences shifts similar to women's, while men who invest less should not display similar preference shifts. Men's closeness to, and investment in, offspring is predicted by both child resemblance to themselves and their self-reported paternity confidence (Anderson 2005; Anderson et al. 1999a, b; Apicella and Marlowe 2004). Paternal investment is also predicted by mating opportunities. Across many species, factors like male phenotype and availability of additional mates predicts parenting effort (Magrath and Komdeur 2003). In humans, a scarcity of females predicts greater paternal investment (Pedersen 1991). Males who can better increase their reproductive success through obtaining additional mating opportunities should trade off parenting effort in favor of mating effort. We should only expect to see differences in mate preferences in fathers if they invest highly in offspring.

Similar to mothers, highly investing fathers should place greater weight on a mate's ability to provide resources and indicators that a mate will not pose a threat to his children. Although men in general place less importance on a mate's current and future ability to obtain and contribute resources, men who invest highly in offspring should be interested in mates who will assist and support their provisioning. They should be less interested in a new mate that will consume their resources at a cost to existing offspring. Step-mothers also pose a risk to step-children, similar to step-fathers. They are more likely to abuse and murder children than biological mothers (Daly and Wilson 1988). Fathers responsible for a significant portion of childcare should prefer new mates who display cues to kindness, interest in their children, and who lack aggression. However, it is unlikely any differences in mate preferences will be as pronounced in fathers as in mothers because even investing fathers generally engage in far less parental care than mothers.

The Effect of Children on Men's Mate Value

As with women, it is important to consider the influence children will have on paternal mate value. Children have a detrimental effect on a mother's mate value. The influence children have on paternal mate value is less straightforward. Although their presence indicates to a woman that some of a man's resources, time, and energy will be devoted to individuals other than herself and her children, his children provide her an opportunity to assess his parenting ability. Having children may even make a man more attractive as a mate because it allows him to demonstrate he is currently a good father and will be a good father to her children, and to any children they have together.

Studies on marriage rates of parents indicate that children have less of a detrimental effect on men's ability to re-partner than women. Divorced and widowed men are more likely to have subsequent intimate relationships and remarry than women (Ahrons 2007; Calasanti and Kiecolt 2007; Lindau et al. 2007). More importantly, when single fathers live with their children, they are far more likely to remarry than single mothers who live with their children (Goldscheider and Sassler 2006). If men's mate value is positively influenced by children, we should expect their mate preferences to adjust accordingly – they may be more selective and interested in higher mate value mates.

Future studies exploring the influence of children on men's mate preferences require assessing paternal investment in existing offspring and determining how children influence men's mate value. Men who engage in low levels of paternal investment should display mate preferences similar to non-fathers. Men engaged in higher levels of paternal investment may demonstrate increased preferences for mates who will help provision and not harm their children, although the magnitude of the differences between non-fathers and fathers should be smaller than differences between non-mothers and mothers. The influence of children on men's mate value remains an important

research question. In addition to providing a cue to parenting abilities, children may influence perceptions of status, resources, and provide a cue to past mating history. Sorting through these possibilities will be necessary to generate predictions about men's mate preferences after children.

WEIRD Populations and Researchers, Children, and Mate Preferences

Comparing mate preferences before and after children requires thinking about the selection pressures that shaped mate preference mechanisms. An extended period of childfree adulthood is a modern phenomenon, particularly for women. Modern birth control and social equality for women have given men and women greater control over reproductive timing and offspring number. A childless 25-year old woman is commonplace in modern, WEIRD (Western, Educated, Industrialized, Rich, Democratic) populations but would have been a rarity through most of human history (Henrich et al. 2010). The design features of mating mechanisms may have been largely shaped in contexts where reproductively viable individuals had children or were already highly invested in the care of siblings and relatives. Researchers must be cautious in distinguishing mate preferences "after" children from "before," which implies a temporal distinction that may be more salient and meaningful to WEIRD researchers than it has been to most humans.

This is especially important to consider with respect to women's mate preferences. Young women high in reproductive value would have been highly sought after as mates, but once mated would have had children quickly. Most of women's mating career would have happened when they were already mothers. Any studies suggesting children alter a woman's mate preferences must parse out the effects of her age, her mate value, and her unmated status on mate preferences, independent from the specific effect the presence of children has. Furthermore, characteristics of the children themselves may be important

considerations. Having particularly unhealthy or burdensome children may negatively influence women's mate value compared to having healthy children, but the presence of healthy children may only negligibly impact her mate value. Children may also actively attempt to manipulate parental mating decisions to benefit their own interests (see Schwarz, this issue ► [“Presence of children”](#)). Any studies of the effect of children on mate preferences may require not just comparing those who have and do not have children but instead require making nuanced predictions about the characteristics of children and how those characteristics affect parents.

Age is another important variable to account for independent of having children. Cross-culturally men prefer younger mates because youth is a cue to reproductive value (Buss 1989). Studies of women in general, and specifically of mothers, have demonstrated that younger women are more likely to remarry after divorce (Bramlett and Mosher 2002; Buckle et al. 1996; Lundberg and Rose 2003). Furthermore, the presence of children provides a cue to age – the older an individual is, the more likely it is that they have children and have more children. Researchers bear the burden of demonstrating that variations in mate preferences are uniquely associated with having children, and not due to age or how having children influences perceptions of age.

Despite these concerns, it is reasonable to think that ancestral humans would have been faced with the adaptive problems of selecting, attracting, and retaining mates at times when they both did and did not have children throughout their life-spans. Even if a man or woman entered a long-term pair-bond when relatively young, their mate could have died, decreased in mate value prompting a mate-switch, or abandoned them. A person's mate value may have increased, or new, better mates appeared, also motivating mate-switching (Buss et al. 2017). It is likely children have acted as a selection pressure in some capacity on mate preferences. However, hypotheses exploring the influence of children on mate preference must consider how the presence of children would have acted as a

selection pressure under circumstances very different from our current environment.

Conclusion

We still know very little about how children alter mate preferences. Mate preferences for resource provisioning ability and for cues that indicate a potential mate is less likely to abuse or threaten current offspring are likely candidates for which we should expect increased preferences in parents, especially mothers. Perhaps even more important will be determining how children influence parental mate value. They likely negatively influence mother's mate value but may have a negligible or positive effect on father's mate value. In this way, children will indirectly influence mate preferences because mate value influences mate preferences. Furthermore, distinguishing mate preferences after children from preferences before may be a WEIRD framing of this area of research interest. Future work in this domain should focus on building rationale that takes into account the environment in which mating mechanisms were shaped. It may be specific characteristics of children, such as their health, that influence mate value, rather than the simple presence or absence of children. In any case, considering how children provide input – either directly or indirectly – to mate preference mechanisms will reveal previously undiscovered nuances to human mate preferences.

Definition

Behavioral strategies designed to thwart a romantic partner's infidelity or defection.

Introduction

Humans have regularly and recurrently over evolutionary history formed long-term committed relationships as part of their sexual strategies, consequently facing the adaptive problem of successfully retaining a mate which they have selected and attracted. Thus, successful mate retention is a key human concern, and its importance is amplified to the degree that mate poachers attempt to lure one's mate away, to the degree one is invested in and dependent on the relationship, and to the degree that one's mate is tempted by the prospect of temporary infidelity or total defection.

Retaining a mate requires solving several adaptive problems, including: preventing a partner from leaving, diminishing a partner's interest in other long-term or short-term relationships, and increasing a partner's interest in the current relationship. As a consequence of the number and complexity of mate retention problems that mated individuals have recurrently faced over human evolutionary history, it is reasonable to expect that humans have evolved a large array of adaptations dedicated to mate retention. The behavioral outputs of mate retention adaptations may be broadly referred to as mate retention strategies.

Successful mate retention involves the maintenance of an exclusive romantic relationship over a long period of time. Thus, mate retention strategies include tactics such as continuously providing reproductively relevant resources that fulfill

the mate preferences and desires of a partner. Failure to fulfill these preferences and desires leads to failure to retain that mate (via extra-pair affairs, breakup, divorce, etc.). The hypotheses that humans have evolved adaptations designed to retain their mates, to ward off mate poachers, and to prevent mate defection has received growing support from empirical studies that have outlined some of the "design features" predicted in advance by evolutionary hypotheses about mate retention adaptations.

Performance of mate retention strategies increases to the degree that an individual perceives the problem of partner infidelity. An individual's perception of this problem is influenced by their own information-processing machinery (i.e., stable individual differences) and by informational inputs about their partner (e.g., partner's mate value) and the context (e.g., relationship commitment). These inputs influence perception of a partner's risk of infidelity because this kind of information has helped individuals assess, and therefore mitigate, a partner's infidelity or defection – on average, over evolutionary history. For example, the problem of mate retention is more severe when mated to a partner who has an unrestricted sociosexual orientation – who is more likely to pursue a short-term mating strategy. Another example is that mate retention effort is sensitive to sex-linked components of a partner's mate value such as youth and physical attractiveness (components of female more than male mate value) and ability and willingness to invest resources (components of male more than female mate value). These and other empirical findings support the general hypothesis that humans have evolved adaptations for mate retention that have psychological design features that motivate individuals to increase or decrease effort allocated to mate retention, depending on specific informational inputs outlined below.

Mate Retention Inventory

Buss (1988) developed the Mate Retention Inventory (MRI), a taxonomy of 104 acts clustered

into 19 mate retention “tactics” ranging from subtle to overt (see Table 1). These tactics are organized into five “categories”: (1) Direct Guarding, (2) Intersexual Negative Inducements, (3) Intrasexual Negative Inducements, (4) Positive Inducements, and (5) Public Signals of Possession. One common way to group the five categories into two overarching “domains” is Intersexual Manipulations (those directed at one’s romantic partner; categories 1, 2, and 4) and Intrasexual Manipulations (those directed at same-sex rivals; categories 3 and 5). Another common way to

group the five categories into two overarching domains is Cost-Inflicting behaviors (those reducing the risk of partner infidelity by lowering a partner’s self-esteem, thereby causing that partner to feel unworthy of the current or any other relationship; categories 1, 2, and 3) and Benefit-Provisioning behaviors (those reducing the risk of partner infidelity by increasing a partner’s relationship satisfaction; categories 4 and 5) (Miner et al. 2009). The MRI is a reliable measure overall and has been used to document the prevalence of mate retention behaviors in various samples,

Mate Retention, Table 1 Mate retention (MR) domains, categories, tactics, and sample items

MR domain	MR category	MR tactic	Sample item
Cost-Inflicting	Direct Guarding ^a	Vigilance	<i>Dropped by unexpectedly to see what my partner was doing</i>
		Concealment of Mate	<i>Refused to introduce my partner to my same-sex friends</i>
		Monopolize Mate’s Time	<i>Would not let my partner go out without me</i>
	Intersexual Negative Inducements ^a	Threaten Infidelity (Jealousy Induction)	<i>Flirted with someone in front of my partner</i>
		Punish Mate’s Infidelity threat	<i>Became angry when my partner flirted too much</i>
		Emotional Manipulation	<i>Threatened to harm myself if my partner ever left me</i>
		Commitment Manipulation	<i>Asked my partner to marry me</i>
		Derogation of Competitors	<i>Cut down the appearance of other men/women</i>
	Intrasexual Negative Inducements ^b	Derogation of Mate to Competitors	<i>Told others my partner was “a pain”</i>
		Intrasexual Threats	<i>Confronted someone who had made a pass at my partner</i>
		Violence Against Rivals	<i>Got my friends to beat up someone who was interested in my partner</i>
Benefit-Provisioning	Positive Inducements ^a	Resource Display	<i>Spent a lot of money on my partner</i>
		Sexual Inducements	<i>Gave in to sexual pressure to keep my partner</i>
		Appearance Enhancements	<i>Made sure that I looked nice for my partner</i>
		Love and Care	<i>Told my partner “I love you.”</i>
		Submission and Debasement	<i>Gave in to my partner’s every wish</i>
	Public Signals of Possession ^b	Verbal Possession Signals	<i>Introduced my partner as my spouse or romantic partner</i>
		Physical Possession Signals	<i>Sat next to my partner when others were around</i>
		Possessive Ornamentation	<i>Asked my partner to wear my ring</i>

^aIntersexual Manipulation

^bIntrasexual Manipulation

including undergraduate populations, newlyweds, and longer-married couples. Further, the MRI shows high congruence between self-reports and partner-reports, indicating that partners can reliably describe one another's mate retention behaviors.

Given the importance of assessing mate retention in various contexts, The Mate Retention Inventory-Short Form (MRI-SF; Buss et al. 2008) was developed to provide researchers with a briefer version of the MRI. The MRI-SF is a 38-item instrument that assesses the same 19 mate retention tactics as the MRI, with the same grouping hierarchy of five mate retention categories, and both sets of two overarching domains. The MRI-SF has demonstrated good reliability and validity in various samples.

Mate Retention and Mate Value

Both types of mate retention (Benefit-Provisioning and Cost-Inflicting) behaviors are motivated by sexual jealousy and have likely minimized reproductive losses for ancestral men and women. Because these reproductive losses vary in magnitude across relationships, men and women allocate effort to mate retention based on characteristics of their current relationship, including their own and their partner's "mate value" – a measure of the comparison between a person's characteristics and the characteristics desired by the opposite sex (e.g., a current or potential partner) – and the discrepancy between the two. Men and women may use assessments of mate value to gauge the likelihood, and consequent costs, of a partner's infidelity or outright relationship defection.

Mate value comprises physical traits (e.g., higher shoulder-to-hip ratio and greater height increase men's mate value, lower waist-to-hip ratio increases women's mate value) and social attributes (e.g., social status, generosity, intelligence, resource earning potential) which may signal, for example, genetic quality, fertility, and likelihood of investing in offspring. The mate value of one's partner predicts one's performance of mate retention directed towards that partner.

For example, men allocate more effort to mate retention when the costs of a partner being unfaithful or permanently defecting from the relationship are especially high or when these events are perceived to be particularly likely. Losing a youthful or more attractive partner may be costlier to men than losing an older or less attractive partner because of the difficulty of replacing a more reproductively valuable partner. Additionally, more attractive partners have more opportunities for infidelity, because they are more desired by the opposite sex. For these reasons, men mated to younger, more attractive women allocate greater effort to mate retention than do men mated to older, less attractive women (Buss and Shackelford 1997), and men allocate more effort to mate retention when they perceive that their partner is more likely to be unfaithful (e.g., Buss and Shackelford 1997; Goetz et al. 2005).

Women's mate value predicts men's mate retention behaviors, particularly Benefit-Provisioning behaviors which require known costs from men (e.g., up-front resource and time investments), as opposed to Cost-Inflicting behaviors which have unknown costs for men (e.g., men may or may not be retaliated against). Benefit-Provisioning tactics such as those in the Positive Inducements category are more frequently performed by men mated to women of higher (vs. lower) mate value. Men invest up-front (i.e., provision benefits) only with a woman that they perceive as being of high enough mate value to warrant their time and resources. Men's reports of their partner's mate value also predicts their more frequent performance of Intersexual Negative Inducements (one category of Cost-Inflicting mate retention), which suggests that men may resort to Cost-Inflicting behaviors with a higher mate value partner as part of increased efforts to retain her, if they cannot afford the known costs of Benefit-Provisioning.

One's *own* mate value also predicts one's performance of mate retention. Men of higher mate value are more likely to perform Benefit-Provisioning mate retention, whereas men of lower mate value are more likely to perform Cost-inflicting mate retention (e.g., Miner et al. 2009). Notably, these relationships depend on *who* is assessing men's mate value and mate retention.

The *discrepancy* between one's mate value and their partner's mate value also predicts mate retention behaviors. Although partners in a long-term relationship tend to be of similar mate value, humans detect and magnify differences when that information is important for assessing risks (and has been a reliable cue for that risk in the ancestral past). Mate value discrepancy between members of a couple may indicate important relationship outcomes such as the risk of partner's infidelity and one's ability to secure a better mate. It is especially important to assess these discrepancies, however small, in the context of a long-term relationship because of the large investment in that relationship (and missed opportunities in other relationships). Indeed, mate value discrepancy predicts several relationship processes, including relationship satisfaction, the perceived likelihood of partner defection, and mate retention behaviors (e.g., Conroy-Beam et al. 2016; Sela et al. *in press*).

Mate Retention Across the Ovulatory Cycle

Women can conceive only during the fertile phase of their ovulatory cycle. Thus, historically, women could have obtained genetic benefits through extra-pair sex only near ovulation but paid costs of extra-pair sex throughout the cycle; while men would have paid heavier costs if their partners had extra-pair sex near ovulation. As conflicts of interest between partners change across the woman's ovulatory cycle, so too do specific and predictable forms of behavioral conflict such as the performance of mate retention behaviors. These intersexual conflicts of interest across the ovulatory cycle may have shaped female interest in extra-pair partners and male efforts to track their partner's whereabouts, both increasing near ovulation (vs. the luteal phase). Further, women mated to men of lower (vs. higher) genetic quality might be expected to exhibit these shifts most strongly because these women could only gain genetic benefits from extra-pair sex. In other words, women mated to a partner of higher genetic quality could also gain

genetic benefits from in-pair sex and, thus, may not need to shift strategies across the ovulatory cycle as much as women mated to a partner of lower genetic quality. Finally, men mated to women that are more (vs. less) attractive are at greater risk of their partner's infidelity across her ovulatory cycle and, thus, should not display shifts in mate retention behavior to the same extent as men mated to less attractive women.

Indeed, several studies have documented such shifts in women and their male partners. Women report greater sexual desire for extra-pair partners near ovulation (vs. the luteal phase), but this is not the case for their sexual desire for their *in-pair* partner (e.g., Gangestad et al. 2002). In fact, women report feeling less committed to their in-pair partner and more resistant to his mate retention efforts (Gangestad et al. 2014) during their high (vs. low) fertility phase.

These shifts in women's psychology pose increased infidelity risk to their in-pair partner during the fertile phase and, thus, it is reasonable to expect that their in-pair partner increase mate retention behaviors accordingly, to counteract this threat. Further, men of low (vs. high) genetic quality are at greater risk of their partner's infidelity at peak fertility because their female partner has the most to gain by pursuing this shifting strategy. Indeed, women report that their in-pair partner performs some mate retention behaviors more frequently during the days leading up to ovulation (vs. the luteal phase). Their in-pair partner is reported to be, for example, more proprietary, vigilant, monopolizing of time, jealous and possessive, attentive and loving (but only when he is reported to be less sexually attractive), as women near peak fertility (e.g., Gangestad et al. 2002; Haselton and Gangestad 2006; Gangestad et al. 2014).

Both ovulatory shifts – increased female extra-pair desires and increased male mate retention behaviors – are moderated by men's sexual (but not investment) attractiveness (e.g., Haselton and Gangestad 2006). Increased male mate retention behaviors during their partner's high fertility phase are also moderated by their partner's attractiveness and her increased extra-pair interest. Men mated to a less (vs. more) attractive woman show a greater increase in jealous and possessive mate

retention behaviors near ovulation (even though more attractive women garner higher-frequency mate retention behaviors across the cycle) (Gangestad et al. 2014; Haselton and Gangestad 2006), and women's increased desire for extra-pair partners positively predicts their in-pair partner's increased self-assertiveness and dependence (Gangestad et al. 2014). Finally, women in their fertile (vs. infertile) phase increase their self-assertiveness and resistance-to-mate-guarding behaviors (specifically, those *unobservable* to their in-pair partner, and especially women who report a greater shift toward extra-pair partner desires) (Gangestad et al. 2014).

In sum, a growing body of evidence suggests that men shift their mate retention behaviors as a counter-strategy to their partner's extra-pair desire shifts, according to men's shifts in risk of their partner's infidelity. Countering men's counter-strategy, women increase their resistance to mate retention when they have the most to gain from extra-pair sex.

Mate Retention and Concurrent Sexual Behaviors

Several studies investigating the relationships between the frequency of various mate retention strategies and sexual behaviors suggest that men and women employ various mate retention strategies concurrently with sexual behaviors. Performance of mate retention behaviors is positively associated with frequency of sexual intercourse with one's partner (e.g., Barbaro et al. 2015). Performance frequency of Benefit-Provisioning mate retention, in particular, is positively associated with time, and interest in, performing oral sex on one's partner (Sela et al. 2015a). Men's performance of mate retention behaviors is positively associated with men's use of semen displacement behaviors (e.g., thrusting, longer copulation duration) as an anti-cuckoldry tactic (Goetz et al. 2005). Thus, these sexual behaviors may be part of a broader mate retention strategy.

Pretending orgasm may be another mate retention strategy, used by women, to prevent a partner's infidelity or defection from the relationship.

Men are attentive and interested in their female partner's orgasm, and women most often report pretending orgasm in order to keep a partner interested or excited and to reduce likelihood of a partner's infidelity or relationship defection. Indeed, women who perceive high (vs. low) risk of their partner's infidelity are more likely to pretend orgasm during copulation with him, and women that are more likely to pretend orgasm also report more frequent performance of mate retention across all five categories (e.g., Kaighobadi et al. 2012).

Mate Retention and Individual Differences

Mate retention behaviors require conscious effort, and individuals are likely to differ in their willingness to engage in such behaviors. Individual differences associated with performing, and with being targeted by, mate retention behaviors include personality dimensions, sex, age, parity, sociosexuality, and relationship status.

Personality Dimensions

Neuroticism is a personality dimension that is hypothesized to reflect high sensitivity to social threats, with high scorers displaying greater social vigilance. Those high on Neuroticism are especially sensitive to social threats, including threats to a romantic relationship, which is likely the reason they allocate more efforts toward mate retention. Individuals high (vs. low) on Neuroticism (or Emotionality) perform more frequent Benefit-Provisioning mate retention (Sela et al. 2015b; Holden et al. 2014; cf. McKibbin et al. 2014). They also perform more frequent Cost-Inflicting mate retention (de Miguel and Buss 2011; Sela et al. 2015b).

Agreeableness is a personality dimension associated with cooperativeness rather than aggressiveness (which is the low end of Agreeableness and which is linked to social cost-inflicting tactics). Thus, Agreeableness should motivate less frequent use of negative, Cost-Inflicting mate retention behaviors and more frequent use of positive, Benefit-Provisioning mate retention

behaviors. Indeed, individuals high (vs. low) on Agreeableness perform less frequent Cost-Inflicting mate retention (Sela et al. 2015b; de Miguel and Buss 2011; Holden et al. 2014; McKibbin et al. 2014). This negative relationship also emerges from *women's report* about their *partner's* Agreeableness – and their *own* Agreeableness – and their partner's Cost-Inflicting mate retention (McKibbin et al. 2014). Individuals high (vs. low) on Agreeableness also perform more frequent Benefit-Provisioning mate retention (Pham et al. 2014; McKibbin et al. 2014; cf. women; Sela et al. 2015b). This positive relationship also emerges from *women's report* of their partner's Agreeableness and Benefit-Provisioning mate retention (McKibbin et al. 2014).

Conscientiousness is a personality dimension that reflects a long-term strategy of delayed gratification and tenacity of goal pursuit (vs. a more impulsive strategy that involves low inhibition against seizing immediate adaptive benefits). Individuals higher on conscientiousness are more likely to acquire long-term resources and successfully negotiate hierarchy, both of which are associated with Benefit-Provisioning mate retention behaviors. Individuals high (vs. low) on conscientiousness perform more frequent Benefit-Provisioning mate retention (Sela et al. 2015b; de Miguel and Buss 2011). Individuals high (vs. low) on conscientiousness also perform less frequent Cost-Inflicting mate retention behaviors in the categories of Direct Guarding, Intersexual Negative Inducements (de Miguel and Buss 2011), and Intrasexual Negative Inducements (Holden et al. 2014). Independently of men's conscientiousness, men who report their female partner is high (vs. low) on conscientiousness also perform more frequent Benefit-Provisioning mate retention (McKibbin et al. 2014).

Openness is a personality dimension characterized by novelty- and complexity-seeking and is associated with creativity. Individuals high (vs. low) on openness perform less frequent Cost-Inflicting mate retention behaviors (Holden et al. 2014). According to *women's report*, it is their own high levels of openness that predict their male partner's decreased Cost-Inflicting mate retention behaviors (McKibbin et al. 2014).

Individuals high (vs. low) on openness also perform more frequent Benefit-Provisioning mate retention (Pham et al. 2014; Sela et al. 2015b).

Extraversion (or surgency) is a personality dimension characterized by positive emotions, exploratory and physical activity, and sociability. Extraversion is also linked with aspects of sexuality, such as trying out different sexual positions and acquiring a variety of different sexual partners. Consequently, it is reasonable to expect that those high on extraversion would effectively use Benefit-Provisioning tactics such as Sexual Inducements toward their partner. It also follows that they are likely to be targets of more frequent mate retention *from* their partners, because they may be perceived as having more social opportunities to be unfaithful. Indeed, individuals high (vs. low) on extraversion perform more frequent Benefit-Provisioning mate retention (Pham et al. 2014; de Miguel and Buss 2011) and more frequent Cost-Inflicting mate retention (de Miguel and Buss 2011). Interestingly, women who report that they are high (vs. low) on surgency also report that *their partner* performs more frequent Cost-Inflicting mate retention behaviors (McKibbin et al. 2014).

Honesty-Humility is a dimension of personality that captures the extent to which individuals are concerned with equality, fairness, and honesty in their interpersonal relationships, and the extent to which they are willing to manipulate, deceive, and exploit others; such that those with higher levels are more likely to treat others fairly and to have difficulty lying. These characteristics seem to influence mate retention such that individuals high (vs. low) on Honesty-Humility perform less frequent Cost-Inflicting mate retention behaviors (Holden et al. 2014), many of which involve manipulation of a partner's emotions and commitment (e.g., "Pleaded that I could not live without my partner").

Dark personality traits (e.g., The dark triad: narcissism, psychopathy, and Machiavellianism) have also been linked to mate retention behaviors. Individuals with high levels of the dark triad traits tend to be antagonistic, self-concerned, callous, and manipulative. Not surprisingly, individuals with high levels of the dark triad traits perform

more frequent mate retention overall and especially more frequent aversive mate retention behaviors such as punishing their partners or acting violently toward romantic rivals (Jonason et al. 2010). Those high (vs. low) in dark triad traits have higher rates of their partner defecting, and this relationship is mediated by their increased mate retention behaviors. Each of the three dark triad traits and its association to mate retention documented in Jonason et al. (2010) is reviewed below.

Narcissism is a personality trait characterized by strong self-focus, sense of entitlement, tendency to exploit others, general lack of empathy, extreme confidence in one's abilities, and excessive need for admiration. Individuals high (vs. low) on narcissism perform more frequent mate retention overall and especially more frequent Cost-Inflicting mate retention. They also perform more frequent Benefit-Provisioning mate retention tactics such as resource display, appearance enhancement, emphasize love and caring, and verbal signals of possession. Although, some tactics may not be used as mate retention per-se or exclusively, given narcissists' tendencies to display their resources, enhance their appearance, and attend to alternative romantic partners.

Psychopathy is a personality trait characterized by antisocial behavior, impulsive thrill-seeking, interpersonal manipulation, and cold affect. Individuals high (vs. low) on psychopathy perform more frequent mate retention overall and especially more frequent Cost-Inflicting mate retention tactics such as monopolize mate's time, threaten infidelity, punish mate's threat to infidelity, derogation of competitors, and intrasexual threats. They also perform more Benefit-Provisioning mate retention tactics such as resource display, appearance enhancement, and verbal signals of possession.

Machiavellianism is a personality trait associated with cynicism, distrust, detachment, and willingness to exploit others or use emotional blackmail and little interest in close, intimate relationships. In a long-term romantic relationship context, men and women with high levels of Machiavellianism employ more frequent Cost-

Inflicting mate retention behaviors (e.g., Brewer and Abell 2015), which are centered on reducing self-esteem of, and harming, a partner. Generally, these individuals should be less likely to engage in Benefit-Provisioning mate retention behaviors (which are mostly centered around developing intimacy and commitment), but in one study Machiavellianism was positively associated with Benefit-Provisioning tactics such as submission and debasement, and physical and verbal signals of possession (Jonason et al. 2010).

Pathological personality features other than the dark triad include: negative affect (concerns the tendency to experience an array of negative emotions), antagonism (refers to aggressive tendencies accompanied by assertions of dominance and grandiosity), disinhibition (includes impulsivity and sensation seeking), detachment (characterized by introversion, social isolation, and anhedonia), and psychoticism (involves a disconnection from reality and a tendency toward illogical thought patterns). These pathological personality features are associated with interpersonal difficulties and with increased mate retention – especially the darker, Cost-Inflicting behaviors (Holden et al. 2015). Individuals with high (vs. low) levels of negative affect are likely to be more concerned about their partner's defection or infidelity and as such employ more frequent mate retention behaviors (primarily Cost-Inflicting, but also Benefit-Provisioning; Holden et al. 2015) in an attempt to mitigate these perceived dangers. Individuals with high levels of antagonism tend to be manipulative, cold, and callous towards others which leads them to perform more frequent Cost-Inflicting mate retention behaviors (Holden et al. 2015). Features of disinhibition such as impulsivity are linked to aggression, and individuals high on this trait perform more Cost-Inflicting mate retention behaviors (but this relationship disappears when allowing co-variation with other pathological personality traits; Holden et al. 2015). Individuals high (vs. low) on detachment are likely to be withdrawn from their romantic partner and avoid intimacy and thus be less investing in maintenance of their romantic relationships; indeed, they perform less frequent mate retention behaviors in both

domains (when allowing co-variation with other pathological personality traits; Holden et al. 2015).

Basic and dark personality traits appear to have a profound effect on strategic behaviors within romantic relationships. Personality dimensions actively influence the tactics that individuals use to impact those around them, including keeping a romantic partner from straying.

Sex Differences

Two key sex differences in mate retention usage have been hypothesized: (1) Men more than women should use resource display mate retention and (2) Women more than men should use enhancing physical appearance mate retention. This hypothesis is based on the logic of Trivers' sexual selection theory, and in particular the link between the two component processes of sexual selection – intrasexual competition and intersexual selection. In order to effectively maintain a romantic relationship, the specific mate retention tactics that individuals perform should target the mate preferences of the opposite-sex partner. Because displays of love are highly valued by both sexes in long-term mating, both sexes should use love displays equally as tactics of mate retention. Because women more than men across cultures prefer status and resources when selecting a mate, mate retention behaviors performed by men more than women should include those under the tactic of resource display (e.g., “Spent a lot of money on my partner”; “Bought my partner an expensive gift”). Men, on the other hand, universally place a greater premium than do women on physical appearance when selecting a mate, although this sex difference is more pronounced in short-term mating than long-term mating. Physical attractiveness provides a wealth of information about a woman's age, health, and fertility. Consequently, mate retention behaviors performed by women more than men should include those under the tactic of enhancing physical appearance (e.g., “Dressed nicely to maintain my partner's interest”; “Made sure I look nice for my partner”). These two hypotheses about sex differences in performance frequency of mate retention tactics have been confirmed in American

samples (e.g., Buss 1988), including married couples (e.g., Buss and Shackelford 1997), a Canadian sample (VanderLaan and Vasey 2008), a Croatian sample (Kardum et al. 2006), a Spanish sample (de Miguel and Buss 2011), an Iranian sample (Atari et al. [under review](#)), and others.

Two other robust sex differences in mate retention performance have been documented across samples and cultures. Men more than women perform more frequent submission and debase-ment mate retention behaviors (e.g., “I went along with everything she said”; “I acted against my will to let her have her way”), (e.g., Atari et al. 2017; Buss and Shackelford 1997; de Miguel and Buss 2011; Kardum et al. 2006). The other consistent sex difference is that men more than women perform more frequent intrasexual threats (e.g., “I threatened to hit the guy who was making moves on my partner”), (e.g., Atari et al. 2017; Buss and Shackelford 1997; de Miguel and Buss 2011; Kardum et al. 2006). The greater use of violence and violent threats are consistent with previous research about the vast majority of same-sex violence being perpetrated by men rather than women.

Further support for the idea that individuals employ mate retention behaviors that target their partner's mate preferences has been documented in homosexual individuals (e.g., VanderLaan and Vasey 2008). For example, homosexual women perform more frequent resource display, and less frequent appearance enhancement, than heterosexual women. This suggests that women perform these tactics to target their partner's sex-specific preferences (i.e., female's prioritization of partner-provisioned resources and lesser emphasis on partner's physical appearance). Homosexual men, on the other hand, perform less frequent resource display mate retention than heterosexual men. Thus, it appears that men perform these behaviors to target partner preferences; this tactic used more frequently toward a man's female partner but less frequently toward a man's male partner.

Age, Relationship Length, and Parity

Age and relationship length tend to be positively associated, and both have been documented to

have negative associations with performance of mate retention. Younger individuals, and individuals that have been in their relationship for a shorter period of time, perform more frequent mate retention behaviors than older individuals and those who have been in their relationship for longer (e.g., Buss and Shackelford 1997; de Miguel and Buss 2011). Kaighobadi et al. (2010) documented a decline in frequency of performing mate retention behaviors in the 3-year period immediately following marriage, which could be a function of age, relationship maturation, relationship commitment, or some combination of these. Another important factor that comes along with aging, and relationships of longer duration, is having children.

Parity, however, has been hypothesized to be *positively* associated with mate retention performance frequency. Men and women should be motivated to remain pair-bonded after having children for two ancestrally important reasons: maintaining the distribution of male-provisioned resources to a woman and her offspring and to protect offspring from infanticide. Indeed, Barbaro et al. (2016) documented that both men and women with genetic children with their current partner perform more frequent individual mate retention behaviors and request more frequent coalitional mate retention (see below) behaviors than men and women without genetic children with their current partner. The magnitude of these associations remain, even after controlling for age and relationship length which were positively associated with parity and negatively associated with performance frequency of mate retention in that sample.

Attachment

Another important individual difference relevant to mate retention behaviors is romantic attachment. Romantic attachment functions to maintain pair-bonds and facilitate reproductive strategies. Romantic attachment bonds influence the ways in which individuals respond to relationship threats and are conceptualized as two continuous and independent dimensions of *anxiety* and *avoidance*. Attachment anxiety reflects a hyperactivation of the romantic attachment system and

is characterized by attempts to attain proximity to a romantic partner. Greater attachment anxiety is associated with hypervigilance to cues of abandonment and rejection by a romantic partner and difficulty disengaging from cues to relationship distress. Attachment avoidance, in contrast, reflects a hypoactivation of the romantic attachment system and is characterized by attempts to evade emotional intimacy and physical proximity to a romantic partner. Greater attachment avoidance is associated with independence and self-reliance that facilitate decreased partner dependence and proximity-seeking. More avoidantly attached individuals are more likely to discount cues of relationship threats relative to more anxiously attached individuals.

Romantic attachment dimensions of anxiety and avoidance are associated with distinct behavioral patterns within romantic relationships – particularly jealousy and infidelity – a link that has led to hypotheses concerning unique associations between mate retention domains and romantic attachment dimensions. Indeed, individuals who are more (vs. less) anxiously attached perform more frequent mate retention behaviors, whereas individuals who are more (vs. less) avoidantly attached perform less frequent mate retention behaviors (e.g., Barbaro et al. *under review*). In another sample of nonclinical individuals, those who scored higher (vs. lower) on borderline personality disorder features – strongly associated with attachment bonds characterized by fear of rejection, lack of trust, hypersensitivity to perceptions of, and hypervigilance in acting on cues of potential threats to relationships – also perform more frequent mate retention behaviors (Tragesser and Benfield 2012).

More anxiously (vs. avoidantly) attached individuals also report greater perceived risk of a partner's likelihood of committing infidelity, and this perception mediates the relationship between anxious attachment and performance frequency of Cost-Inflicting mate retention (Barbaro et al. *under review*).

It is suggested that more anxiously attached individuals perform mate retention behaviors more frequently because these individuals are hypervigilant to cues of partner abandonment

and infidelity. In contrast, more avoidantly attached individuals perform less frequent mate retention behaviors, more generally, because these individuals underestimate the extent to which behaviors are indicative of infidelity and are motivated to evade emotional and physical intimacy with a romantic partner.

Relationship Status and Sociosexuality

Theoretically, relationship status, especially the degree of relationship commitment, is expected to influence mate retention efforts such that individuals in more committed, long-term relationships should exert more effort to keep their romantic partner than individuals in less committed, short-term relationships. Indeed, individuals in a more (vs. less) serious, committed romantic relationship perform more frequent mate retention behaviors overall (e.g., Buss 1988). One interesting exception is the Threatening Infidelity mate retention tactic, which is performed more frequently by individuals in a *less* committed relationship (de Miguel and Buss 2011). This finding is consistent with the hypothesis that jealousy induction is a tactic more heavily used by individuals in circumstances in which they are more committed to their relationship than their partner. Individuals more committed than they perceive their partner to be may induce jealousy in an attempt to increase the commitment of their partner.

Another aspect of relationship commitment is perception of a partner's characteristics. One important indicator of a partner's commitment is their standing on sociosexuality, a dimension that reflects a wide range of sexual behaviors and attitudes toward sex, which is defined as the degree to which individuals require emotional closeness and commitment before having sex. Sociosexually restricted individuals prefer commitment and closeness with their romantic partner prior to engaging in sex, while unrestricted individuals tend to engage in sex without commitment or closeness. Accordingly, sociosexually unrestricted (vs. restricted) individuals are more likely to get involved in extra-pair relationships, are more sexually assertive, engage in socially dominant behaviors (e.g., maintaining eye contact and close physical proximity), and are more responsive to situational sexual cues.

A partner that is less (vs. more) sociosexually restricted poses a greater risk of infidelity and should be targeted by more mate retention efforts. Indeed, individuals with a less (vs. more) sociosexually restricted partner perform more frequent mate retention behaviors toward that partner (Kardum et al. 2006). Interestingly, women mated with men who are less sociosexually restricted perform more frequent Intersexual Manipulation mate retention (those behaviors targeted toward their partner), whereas men mated to women who are less sociosexually restricted perform more frequent Intrasexual Manipulation (those behaviors designed to fend off mate poachers) and especially the tactic of violence against rivals (Kardum et al. 2006).

Coalitional Mate Retention

The MRI measures individual's performance of behaviors that aim to thwart a partner's infidelity or defection. However, others may perform behaviors to assist an individual with this goal as well. Coalitional mate retention involves behaviors that one's *allies* perform to reduce the likelihood of one's partner's infidelity or defection. Pham et al. (2015a) developed the coalitional mate retention inventory, which assesses the occurrence frequency of coalitional mate retention behaviors across several tactics.

Coalitional mate retention can overcome some of the costs associated with individual mate retention but may be uniquely costly in other ways. For example, if one performs excessive individual mate retention, one's partner may perceive them as overbearing, excessively jealous, or mistrustful. Coalitional mate retention can overcome these costs by having a friend perform mate retention, and thereby reducing the negative impression on one's partner. Coalitional mate retention can also overcome geographic (e.g., long-distance relationships) and time (e.g., restrictive work schedules) constraints of individual mate retention. Potential costs to coalitional mate retention include same-sex allies poaching a romantic partner, because of their increased interaction, and because requesting help from an ally with mate retention may signal that the relationship is

unstable. Another potential problem is a same-sex ally sabotaging the relationship in order to become romantically involved with the individual that had requested the help.

The quality of the relationship between an individual and their ally is associated with the likelihood of requesting coalitional mate retention (Pham et al. 2015b). Relationship quality of friendships involving women are positively correlated with requests of coalitional mate retention, but relationship quality within male-male friendships is *negatively* correlated with requests of coalitional mate retention. This sex difference suggests that because men, relative to women, inflict heavier retaliatory costs on mate poachers, coalitional mate retention may be less likely to be deployed between male friends in order to avoid risking the loss of an important social resource.

One's standings on several personality dimensions are also correlated with one's requests of coalitional mate retention (Pham et al. *in press*). For example, individuals lower in honesty-humility and higher in extraversion report less frequent requests for coalitional mate retention. Men (but not women) higher in emotionality and lower in openness more frequently request coalitional mate retention, suggesting that coalitional mate retention might be employed more frequently by men who are less willing to communicate with their partner. It appears, more generally, that dishonest individuals are more likely to request coalitional mate retention, suggesting that coalitional mate retention – as compared to individual mate retention – is associated with manipulative and deceitful personality dimensions.

Conclusion

Mate retention strategies are the behavioral tactics that individuals employ to maintain their romantic relationships by reducing the probability of infidelity or defection by their current romantic partner. The majority of research in this area has investigated the mate retention behaviors that individuals perform, as assessed by the MRI and MRI-SF. Recent studies have widened the scope of mate retention strategies to include other sexual behaviors (e.g., oral sex) and behaviors employed by one's allies

(i.e., coalitional mate retention), providing new insights about the complexities and context specificity involved in decisions about how to best keep an exclusive romantic relationship.

Mate retention strategies are outputs of an evolved psychology designed to address one of greatest adaptive challenges humans have recurrently faced in long-term relationships: keeping a desired partner from straying. The hypothesis that humans have evolved adaptations designed to hold on to their mates, ward off mate poachers, and prevent mate defection has received growing support from empirical studies that have outlined some of the design features predicted in advance by evolutionary hypotheses about mate retention adaptations (e.g., sensitivity to partner's risk of infidelity as indicated by their mate value and sociosexuality). Applying an evolutionary framework to the study of mate retention has proven fruitful over the past few decades, and there remain open many profitable avenues of research in this area.

Mate Retention After Children

Nicole Barbaro

Department of Psychology, Oakland University,
Rochester, MI, USA

Definition

Mate retention effort after having children that functions to maintain the pair-bond between parents.

Introduction

Several features of normative human life history are unique among the primate order and are particularly unique among our great ape relatives (e.g., chimpanzees, gorillas). For instance, human mothers nurse offspring for a shorter period of time, who have shorter inter-birth intervals, an extended juvenile period, later age at sexual maturity, and longer lifespan relative to

nonhuman primates (Yamagiwa 2015). The most striking human life history traits include the extraordinary length of infant dependency and the formation of long-term pair-bonds.

Pair-bonding in humans evolved as a result of two opposing evolutionary forces: the transition to bipedal locomotion and the evolution of large brains in the genus *Homo*. The evolution of substantially larger brains in *Homo* over the preceding four million years, coupled with the evolution of bipedal locomotion approximately four million years ago, may account for the long duration of infant dependency in humans. Because bipedal locomotion consequently results in a relatively smaller birth canal, a strong selection pressure was imposed on the size of the brain at which human infants could pass safely through the birth canal. Because of these opposing evolutionary forces – smaller birth canal and larger brains – human infants are born at a much earlier stage of brain development than other great apes (Lovejoy 2005). Human infants are, more generally, precocial at birth, but an underdeveloped brain and extreme duration of infant dependency constitute altricial features (Martin 2013). This unique set of traits in human infants may have been a primary selection pressure for pair-bonding in humans (Yamagiwa 2015).

Biparental Care

Humans are among the 3 % of mammals that form long-term pair-bonds, and unique among our great ape relatives. Because of human infants' extreme dependency on caregivers for survival, pair-bonding in humans facilitates biparental care, which increases probability of offspring surviving to reproductive age. Paternal investment is common in humans, although the degree to which fathers invest in their offspring varies cross-culturally (Fernandez-Duque et al. 2009). Variation in paternal investment is associated with the local ecology (e.g., resources, morbidity, and mortality) and the social environment (e.g., availability of mates, availability of alloparents) (Fernandez-Duque et al. 2009; Hewlett 1991; Quinlan 2007).

Biparental investment can reduce the likelihood of child mortality and other negative outcomes for children. In the Tsimane of Bolivia, the death of a father corresponds with higher mortality rates for children (Winking et al. 2011). In the Ache of Paraguay, children whose genetic father lived with them had a mortality rate of 20 %, whereas father absence was associated with a mortality rate of 45 % (Hill and Hurtado 1996). Similarly, in preindustrial countries prior to the twentieth century, father absence was related to increased child mortality (Geary 2000).

Biparental investment and remaining pair-bonded are beneficial to both men and women for offspring survival. A mother's death early in a child's life – especially during the period of time in which a mother is nursing her offspring – has a profound and negative impact on offspring survival (Sear and Mace 2008, for review). And, men with children reliably secure higher fitness pay-offs for allocating greater effort to mate retention and parenting than they do for allocating greater effort to extra-pair mating (Hawkes et al. 1995). But, how exactly does remaining pair-bonded facilitate offspring survival? Two non-mutually exclusive hypotheses concerning the selection pressures that led to biparental investment in humans have emerged in the literature: the *male provisioning hypothesis* and the *male-male competition hypothesis*.

Male Provisioning

The male provisioning hypothesis proposes that men remain pair-bonded to provide their offspring with resources, such as food (Quinlan 2008). Fisher (1987) postulates that the period of time during which a woman nurses her infant may be a “critical period” for paternal investment, in particular. Over humans' evolutionary history – and still today in traditional hunter-gatherer societies – women's foraging returns, on average, account for higher caloric return than do men's hunting returns. Research among the Hadza foragers showed that during the period in which a woman nurses her offspring (about 2–4 years) her foraging returns significantly decreased from average

levels (Marlowe 2003). However, Hadza men with nursing wives compensate for diminished foraging returns by sharing fewer hunting returns with the social group and redirecting these hunting returns to their family.

Men's hunting abilities can also indirectly benefit the nutritional welfare, and therefore survival prospects, of their offspring. In the Hadza of East Africa, for example, a man's own hunting success does not directly impact the nutritional status of his offspring. However, better hunters are, on average, married to better foragers. And, because women's foraging returns account for greater caloric intake than do men's hunting returns, better foraging wives have a direct impact on the nutritional status and, thus, the survival prospects of their children (Hawkes et al. 2001). Therefore, better hunters are able to acquire higher-quality mates – which directly benefits the welfare of their children. These findings demonstrate that both women and men can benefit from pair-bonding and paternal investment (Quinlan and Quinlan 2007, 2008).

Moreover, research further demonstrates how paternal investment, specifically, can indirectly benefit the welfare of offspring. In a cross-cultural ethnographic analysis, paternal investment was positively related to the duration that a woman nurses her infant (Quinlan and Quinlan 2008). Increases in paternal investment may afford women the opportunity to nurse their infants for a longer period of time – which is reliably linked with beneficial developmental outcomes in children.

Male-Male Competition

The male-male competition hypothesis emphasizes a man's role as protector, rather than an investor, of his partner and offspring (Hawkes 2004). Because human infants are extremely dependent on caregivers and require high levels of parental investment for a prolonged period of time, harassment and violence from other adult men, such as infanticide, can impose substantial costs on women and their offspring (Blurton Jones et al. 2000) via abduction, injury, or death.

By remaining pair-bonded following the birth of offspring, a woman depends on the offspring's father to protect her and her offspring from violence and infanticide by other adult men. Married women are at lesser risk of violence from other men (Wilson and Mesnick 1997). Further, a woman with offspring from a previous relationship begins a new relationship with an unrelated male; risk for domestic violence – toward the woman and the offspring – significantly increases (Daly and Wilson 1994). Both men and women can benefit from remaining pair-bonded when they have children because infanticide directly and negatively impacts men's and women's reproductive success.

In nonhuman primates, when a new male usurps a group, he might kill existing offspring to whom he is genetically unrelated. Infanticide brings females into estrus and affords the new male paternity of future offspring (Muller and Wrangham 2009). Infanticide, unfortunately, also occurs in humans. The rate of infanticide in humans is highest when a stepfather – who is not genetically related to a woman's children – is present and when children are younger in age (Daly and Wilson 1994; Weekes-Shackelford and Shackelford 2004). Among the Ache of Paraguay, infanticide is an important cause of child mortality (Hill and Hurtado 1996).

Research has also shown that women prefer dominant men in the context of male-male competition, which is a demonstration of the male's ability to protect her from rival males (Snyder et al. 2008). And, cross-culturally, women prefer high-status men that signal dominance and prestige as long-term partners (Conroy-Beam et al. 2015) – further cues of the man's ability to protect a woman and her offspring from other aggressive men.

Mate Retention Effort

Both the male provisioning hypothesis and the male-male competition hypotheses emphasize how biparental care and pair-bonding can improve the probability of an offspring surviving to reproductive age. Although the specific

selection pressures that facilitated biparental investment in humans are debated, both hypotheses suggest that men and women can both benefit by remaining pair-bonded (at least in the initial years following birth of offspring). Additionally, both hypotheses suggest that men and women are both motivated to remain pair-bonded following birth of offspring and may allocate greater mate retention effort to prevent relationship dissolution.

Mate retention in humans is designed to reduce the risk of a romantic partner committing infidelity and protection against relationship dissolution (Buss 1988). Partner infidelity can inflict costs on men and women and is a leading cause of relationship dissolution. When children are introduced into a relationship, partner infidelity may impose greater costs on men and women than when children are not present. For example, a woman whose partner defects from the relationship is at risk of male violence toward her and her offspring. In ancestral environments and hunter-gatherer societies, a man's defection from the relationship can reduce male-provisioned resources and adversely affect offspring nutrition. A man whose partner defects from the relationship increases the likelihood of offspring mortality, whether by decreasing nutritional welfare of his offspring or by infanticide committed by other men.

Men and women deploy various mate retention strategies concurrently to prevent a romantic partner from defecting from the relationship (Barbaro et al. 2015; Pham et al. 2015). One strategy is *individual mate retention* (Buss 1988). Individual mate retention behaviors are performed alone and function to maintain a romantic relationship. Individual mate retention behaviors can be directed toward one's primary partner or can be directed toward intrasexual rivals. Individual mate retention behaviors can also be positive or socially acceptable behaviors that, more generally, function to reduce the risk of partner infidelity by increasing a partner's relationship satisfaction. But, also, individual mate retention behaviors can be negative and even violent that function to reduce the risk of partner infidelity by lowering a partner's self-esteem, thereby causing that partner to feel unworthy of the current or other

relationship domains (Miner et al. 2009). Another mate retention strategy is *coalitional mate retention* (Pham et al. 2015), whereby an individual requests that a close ally such as a friend performs mate retention behaviors. Coalitional mate retention can reduce the risk of a partner being perceived as “overbearing” or jealous (Pham et al. 2015).

The various normative life history traits that are unique to humans relative to nonhuman primates suggest that mate retention effort may differ for individuals with children as compared to individuals that do not have children. Research conducted by Barbaro and colleagues (2016) recruited over one thousand adult participants that were in a committed, heterosexual relationship from across the United States. In an online survey, participants indicated whether they had at least one genetic child they shared with their current partner and reported the frequency in which they performed various individual mate retention and coalitional mate retention behaviors. The results indicate that men and women with at least one genetic child with their current partner perform more frequent individual mate retention behaviors than men and women who did not have children with their current partner. Additionally, men and women with at least one genetic child with their current partner requested more frequent coalitional mate retention behaviors from both their male friend and female friend than men and women who did not have children with their current partner. That mothers and fathers perform more mate retention than individuals without children points to the importance of both the male provisioning and male-male competition hypotheses in the maintenance of pair-bonds and the ways in which biparental investment facilitates offspring survival in humans.

Conclusion

Pair-bonding in humans originated from the evolution of larger and larger brains in *Homo* and the consequent long duration of infant dependency (Yamagiwa 2015). Pair-bonding in humans facilitates biparental care and promotes offspring

survival. Following the birth of a child, men and women are motivated to remain pair-bonded. The “critical period” in which a woman nurses her offspring may be especially important in regard to biparental investment. Men, in particular, will compensate for reduced foraging returns by their wives during early years. Men also provide protection for their partner and offspring from potentially aggressive men. And, men and women both exert greater mate retention effort to thwart partner infidelity and prevent relationship dissolution when they share children together, relative to men and women in committed relationships with no children. Because of unique life history traits in humans, it is likely that remaining pair-bonded following the birth of offspring increased survival prospects of offspring over deep evolutionary time and, thus, was beneficial to both men’s and women’s ultimate replicative success.

Definition

The predictive utility of romantic attachment on performance frequency of mate retention behaviors—behaviors that reduce the likelihood of partner infidelity and/or relationship dissolution.

Introduction

Men and women often form long-term pair-bonds that may span months to years in duration.

Individuals perform mate retention behaviors to reduce the likelihood of a romantic partners infidelity or dissolution of the established relationship (Buss 1988). Performance frequency of mate retention behaviors varies across individuals as a function of dyadic factors and individual differences. Romantic attachment is an individual difference factor that has been documented to predict the frequency with which an individual performs mate retention behaviors (Barbaro et al. 2016; Barbaro et al. *in press*).

Mate Retention and Romantic Attachment

Humans are a socially monogamous species. Men and women typically form multiple, subsequent pair-bonds over the lifespan. Individuals, however, may end a relationship with a partner to pursue a relationship with a new partner, or individuals may surreptitiously pursue extra-pair copulations while concurrently in a relationship with a primary partner (Buss et al. 2017). A romantic partner's infidelity inflicts costs on men and women. A man whose partner commits sexual infidelity is a risk for cuckoldry – the unwitting investment into offspring to whom he is genetically unrelated (Shackelford 2003). A woman whose partner commits infidelity risks losing partner-provisioned resources for her and her offspring (Trivers 1972).

Men and women are motivated to prevent a romantic partner's infidelity or the dissolution of their current romantic relationship. One strategy men and women use toward this end is *individual mate retention*. Individual mate retention refers to behaviors that an individual performs alone that reduce the likelihood of partner infidelity or relationship dissolution (Buss 1988). Mate retention behaviors can be classified into two domains of Benefit-Provisioning and Cost-Inflicting (Miner et al. 2009). Benefit-Provisioning mate retention are behaviors that function to increase the satisfaction of an individual's partner thereby reducing the partner's motivation to commit infidelity or end the relationship. Cost-Inflicting mate retention, in contrast, are comprised of behaviors that

function to decrease the self-esteem of the romantic partner thereby reducing the partner's feelings of being worthy of another romantic partner.

Performance frequencies of mate retention behaviors vary as a function of dyadic-level and individual level behaviors, including relationship duration, age, biological sex, infidelity risk, mate value, and available alternatives, for example. Romantic attachment towards a partner has also been documented to affect performance frequencies of mate retention behaviors. Evolutionary perspectives on romantic attachment (Del Giudice 2009; Hazan and Zeifman 1999) posit that attachment bonds function to maintain pair-bonds between romantic partner by regulating emotional and behavioral responses to perceived relationship threats. Romantic attachment bonds are conceptualized along the two dimensions of attachment *anxiety* and attachment *avoidance* (Fraley et al. 2000). Attachment anxiety reflects hyperactivation of the romantic attachment system such that individuals scoring higher on this dimension report more chronic jealousy, vigilance to cues of abandonment and rejection by their partner, and more intense negative emotional reactions. Attachment avoidance reflects hypoactivation of the romantic attachment system such that individuals scoring higher on this dimension report lesser relationship commitment, a greater need for independence within the relationship, and are more attentive to alternative romantic partners.

Research investigated whether attachment bonds influence perceptions of infidelity-type behaviors (Kruger et al. 2013) by asking participants to rate whether various types of interactions with others (i.e., casual social interactions, close relationship behaviors, and sexual and erotic interactions) were considered infidelity. More anxiously attached individuals rated close relationship behaviors as cueing infidelity, whereas more avoidantly attached individuals discounted the relevance of sexual and erotic interactions with others as cues of infidelity. These results demonstrate that individual's attachment bond toward their romantic partner influences their perception of their partner potential infidelity.

An individual's perception of their partner's likelihood of infidelity is a strong predictor of

the frequency with which an individual performs mate retention behaviors. Because attachment anxiety and attachment avoidance are associated with varying perceptions of partner infidelity (Kruger et al. 2013), Barbaro et al. (2016) hypothesized that attachment anxiety and attachment avoidance may reliably be associated with performance frequencies of mate retention behaviors. The results of a survey studies conducted with men and women residing in the United States (Barbaro et al. 2016) and residing in Iran (Barbaro et al. *in press*) documented that, overall, attachment anxiety is associated with more frequent performance of mate retention behaviors, whereas attachment avoidance is associated with relatively less frequent performance of mate retention behaviors. In a subsequent survey study conducted in the United States (Barbaro et al. *in press*), it was found that an individual's perception of their partner's potential infidelity mediates the association between attachment anxiety and performance frequencies of mate retention behaviors.

Research on the associations between romantic attachment and performance of mate retention behaviors is limited. Empirical findings thus far, however, are consistent with the notion that the association between attachment anxiety and mate retention behaviors is explained, in part, by a hypervigilance to rejection cues and potential infidelity cues by a romantic partner, which may motivate the performance of mate retention behaviors. Attachment avoidance, in contrast, appears to inhibit an individual's perception of their partner's infidelity, possibly due to the hypoactivation of the romantic attachment system. Experimental and dyadic research designs could profitably be pursued to more thoroughly elucidate the associations between romantic attachment and mate retention behaviors.

Conclusion

Individual difference factors influence the frequency with which men women perform mate retention behaviors to reduce the likelihood of their romantic partner committing infidelity or dissolution of the relationship (Buss 1988).

Research investigating the influence of an individual's attachment anxiety and attachment avoidance on performance frequency of mate retention behaviors has revealed that, more generally, attachment anxiety is associated with increased perceptions and a partner's future infidelity and more frequent performance of mate retention behaviors, whereas attachment avoidance is associated with relatively less frequent performance of mate retention behaviors (Barbaro et al. 2016, *in press*).

Definition

The strategies used to ensure the partner's permanence and fidelity in a long-term relationship.

Introduction

Most living beings invest energy, time, and resources in reproductive aspects, especially those related to the selection and retention of partners (Buss 1988; Buss and Shackelford 1997). Partner retention is often not an adaptive problem, since relationships tend to be short in nonhumans in general. Among humans, relationships with the same partner over a long period of time are a central aspect of many individuals' lives (Barbaro et al. 2015). Given the importance of relationships and their implications for survival and well-being, many individuals invest significant time and resources in maintaining these relationships. Some of the strategies used to maintain relationships are to prevent partners from abandoning the relationship or being attracted by rivals.

Men and women present various strategies for retention of their partners. Some associated goals are: to save the energy directed to attracting and conquering a new partner, to ensure parental investment in the offspring, to ensure investment of resources in the partner, and to increase the chances of reproductive success (Gallup Jr and Frederick 2010). In addition, partner retention strategies are associated with various aspects of romantic relationships, such as the frequency of sexual intercourse and violence between partners (Barbaro et al. 2015; Buss 1988).

Composition of Retention Strategies

From an evolutionary perspective, in addition to aspects such as well-being and belonging, long-term relationships are advantageous mainly because: (1) for men, there is a guarantee of transmission of genes with greater control and certainty of paternity; (2) for women, there is

control of the investment and care of the partner towards the offspring (Gallup Jr and Frederick 2010). Thus, both sexes make efforts to retain the partner in long-term relationships. Partner retention happens through various behaviors (or tactics) made with the objective of reducing the probability of the partner engaging in affective or sexual relationships with third parties or leaving the relationship. It involves, for example, attempting to monopolize partner time or slander potential competitors (Buss 1988; Buss and Shackelford 1997).

Buss (1988) proposed the first model to systematize partner retention behaviors in humans. The retention was operationalized through 19 tactics, organized into five strategies and distributed in two domains. Each of the five strategies is composed of some tactics; they are: (1) direct guarding, that is, vigilance, monopolize mate's time, and concealment of mate; (2) intersexual negative inducements, which include threaten infidelity, punishment mate's threat to infidelity, emotional manipulation, commitment manipulation, and derogation of competitors; (3) intra-sexual negative inducements, consisting of derogation of mate to competitors, intrasexual threats, and violence; (4) positive inducements, consisting of submission and debasement, emphasize love and care, resource display, sexual inducements, and enhancing physical appearance; and (5) public signals of possession, which include verbal signals of possession, physical signals of possession, and possessive ornamentation.

The domains organize the strategies into the ones that are costly and the ones that result in benefits (Miner et al. 2009). The strategies of the first domain are those that seek to reduce the risk of partner infidelity by reducing their self-esteem, making them feel sexually or emotionally undesirable, and include the following strategies: direct guarding, intersexual negative inducements, and intrasexual negative inducements. In turn, benefit-provisioning mate retention strategies seek to increase partner satisfaction with the relationship, they are the positive inducements and the public signs of possession (Buss 1988).

Differences Between Sexes in the Use of Retention Strategies

Research has identified gender differences in the use of partner retention tactics (Buss 1988; Buss and Shackelford 1997). For example, men, more than women, tend to resort to exposure of resources, while women, more than men, resort to investments in physical appearance (Atari et al. 2017; Buss and Shackelford 1997; Lopes et al. 2016). These differences corroborate the evolutionary hypotheses that men tend to choose women who appear to have good reproductive capacity prioritizing specific physical aspects related to attractiveness. Women tend to choose partners with characteristics that indicate a greater ability to obtain resources.

Some other differences in the use of strategies include: (a) men with greater partner value use more beneficial strategies and fewer costly strategies compared to men with lower value (Miner et al. 2009); (b) men use more retention strategies with younger or more attractive women (Buss and Shackelford 1997); (c) women married to men with higher incomes use more retention strategies (Buss and Shackelford 1997); and (d) men who suspect partner's infidelity use more retention strategies (Buss and Shackelford 1997). Several factors other than gender differences can help in understanding the differences in the use of retention strategies, individual and contextual factors, such as the reproductive fitness of the individuals, the partner's level of fertility, the operational sex ratio of the environment, the presence of friends within the environment. Thus, research on the topic can help in understanding human romantic relationships and the processes underlying partner selection.

Conclusion

Attracting and securing a partner requires time, energy, and resources. Retention strategies emerge to address threats to the relationship, with the goal of reducing the likelihood of partner abandonment or infidelity. From an evolutionary point of view, retention strategies were selected to

solve these two problems (i.e., infidelity and abandonment) in long-term romantic relationships. They include a wide range of tactics that can be costly or beneficial to the partner. The frequency and intensity of these strategies vary according to gender differences, but also individual and contextual differences. Research on partner retention strategies can provide valuable insights into the workings of romantic relationships.

Definition

Mate retention tactics represent efforts devoted to retaining a long-term mate, preventing partner's infidelity or defection.

Introduction

Humans usually maintain an intimate sexual bond with the same partner for years or decades. Long-term romantic relationships are one of the most common mating arrangements and a central aspect of many individuals' lives (Barbaro et al. 2015; Buss 2003). Mate retention in this relational arrangement is an evolutionary adaptive problem. People invest energy, time, and resources in reproductive aspects, especially those related to the selection and retention of partners (Buss and Shackelford 1997). Considering this, Buss (1988) proposed a model that systematized human mate retention behaviors, describing 19 tactics. Each of these tactics group together a set of behaviors such as cry in front of a partner to control it (e.g., emotional manipulation) and to gift with jewelry (e.g., possessive ornamentation).

Tactics of Mate Retention

Benefits of mate retention in long-term romantic partnerships include greater chances of survival

for individuals and their offspring, greater certainty of paternity for men, lower risk of loss of partner investment, and greater provision of resources for women (Buss 2003). Tactics are the operationalization of the mate retention behaviors. All of them aim to decrease the likelihood of partner infidelity or the end of the long-term relationship, through, for example, the slander of potential competitors or monopolizing partner time (Buss and Shackelford 1997). Mate retention tactics can be relatively positive, such as praise or bestowing gifts on the partner, or negative, such as the use of threats or punishments.

Buss (1988) proposed the first systematic model of partner retention behaviors in humans. Originally, these behaviors were classified into 19 tactics, organized into 5 strategies, and distributed in 2 domains.

The first of these domains, which refers to intrasexual manipulations and is composed of the tactics directed toward the partner, includes three strategies: (1) direct guarding (vigilance, monopolization of mate's time, and concealment of mate); (2) intersexual negative inducements (jealousy induction, punishment of mate's threat to infidelity, emotional manipulation, commitment manipulation, and derogation of competitors); and (3) positive inducements (resource display, sexual inducements, appearance enhancement, emphasis of love and caring, and submission and debasement). The second domain, which is related to intersexual manipulations and is composed of the tactics directed toward same-sex competitors, includes two strategies: (4) public signals of possession (verbal possession signals, physical possession signals, and possessive ornamentation) and (5) intrasexual negative inducements (derogation of mate to competitors, intrasexual threats, and violence against rivals).

In addition, Miner et al. (2009) suggested organizing the five strategies into two other domains: cost-inflicting mate retention (i.e., direct guarding, intersexual negative inducements, and intrasexual negative inducements), which seeks to reduce the risk of partner infidelity, making him/her feeling less attractive, and benefit-provisioning mate retention (i.e., positive inducements and public signals of possession),

which seeks to reduce the risk of infidelity by increasing relationship satisfaction.

Lopes and Shackelford (2018) found evidence of the relationship between the modes of cost-inflicting mate retention tactics and benefit-provisioning mate retention tactics. Participants formed three mate retention clusters or strategies: (1) disengaged (i.e., rare benefit-provisioning and cost-inflicting), (2) exhaustive (i.e., frequent benefit-provisioning and cost-inflicting), and (3) benevolent (i.e., frequent benefit-provisioning and rare cost-inflicting). Moreover, the results indicated that women, more than men, use a disengaged mate retention mode, and men, more than women, use a benevolent mate retention mode. Individuals who do not have enough resources (e.g., time, money) to use benefit-provisioning behaviors can use more cost-inflicting behaviors to retain their romantic partner; or they may resort to a disengaged strategy (i.e., low use of mate retention tactics).

Sex Differences in Use of Mate Retention Tactics

Mate retention behaviors are sex-differentiated: men and women tend to use different strategies to retain their partners. Such differences corroborate the evolutionary hypotheses. While men prioritize physical aspects related to attractiveness in choosing women who appear to have a good reproductive capacity, women seek to choose partners with characteristics that indicate a greater ability to acquire resources. In general, men use more resource display and protection strategies, and women invest more in appearance enhancement and reproductive value (Atari et al. 2017; Buss 1988; Buss and Shackelford 1997; Lopes et al. 2016). For example, differences in the use of tactics include men report less frequent use of cost-inflicting tactics than do women (Lopes et al. 2016; Miner et al. 2009); women more than men use jealousy induction to retain their partners (Buss 1988; Buss and Shackelford 1997; Lopes et al. 2016); and men who suspect a partner's infidelity perform more retention strategies (Buss and Shackelford 1997).

Different uses of mate retention tactics may be linked with reproductive fitness, fertility, sex ratio, and relationship satisfaction. For instance, benefit-provisioning tactics are positively related to relationship satisfaction, while cost-inflicting tactics are negatively associated (Atari et al. 2017; Lopes and Shackelford 2018). Cost-inflicting tactics are riskier than benefit-provisioning because they increase the chances of relationship defection (Miner et al. 2009) and bring negative consequences for the partner's health (Devries et al. 2013). Research on the use of mate retention tactics can help in understanding human romantic long-term relationships and the processes underlying partner selection. In addition, mate retention tactics knowledge may be useful in contexts such as marital therapy or counseling.

Conclusion

Humans usually engage in long-term monogamous relationships. Mate retention is an evolutionary adaptive problem that requires an investment of time, energy, and resources of individuals. Tactics are groups of behaviors that refer to a retention intent, such as jealousy induction and physical possession signals. The Buss (1988) model cataloged 19 major tactics, which may be cost-inflicting or benefit-provisioning. They are used as a protective strategy against threats to the relationship (e.g., partner defection or infidelity). The engagement in one of these tactics is linked to individual and contextual factors, such as differences between the sexes. Research into mate retention tactics can provide valuable insights about long-term relationships, besides subsidizing practical interventions (e.g., marital therapy).

Definition

Mate selection has been a topic of great interest and has gained much attention from diverse fields (Zhang et al. 2015, 2016). Mate selection strategies overlap with reproductive strategies that encompass a broad set of behaviors involving the timing of reproduction and the trade-off between quantity and quality of offspring (Buss and Schmitt 1993). Weatherhead and Robertson (1979) proposed the sexy son hypothesis claiming that females are assumed to compensate for the survival of their offspring by increasing the number of descendants produced (Huk and Winkel 2008). The sexy son hypothesis also implies that a potential mate's capability as a parental caregiver are irrelevant to his value as the potential father or the female's descendant.

Introduction

Darwin's theory with regard to the process of sexual selection is the foundation of current theories on the evolution of mating systems. Darwin (1871) thinks that the evolution of characters enhanced its ability to obtain mates. Implicit in this concept is that individuals of each sex differ from one another with respect to characteristics that affect the fitness they will confer on another individual if chosen as a mate. Consequently, the existing selection pressure will promote the evolution of techniques for males to show off their superior characteristics and for females to distinguish the good characteristics from the bad (Weatherhead and Robertson 1979). Trivers, in his review of sexual selection and the role of parental investment, concludes that sexual selection has the same effect only if the investment of each sex in its offspring is approximately equal. Otherwise, sexual selection among each sex will be unbalanced. For example, if females put more effort than males, the competition among males to

increase their frequency of mating will be high. Thus, sexual selection among males will be strong. As Trivers (1972) points out, females initially have a much higher investment in terms of the energy supplied to each ovum relative to the very small amount of energy devoted by the male to each sperm. The difference in the relative contributions of each sex increases due to the limited role played by the male in rearing the young, especially in highly polygynous mating systems. Consequently, in such systems sexual selection will act much more strongly on the male. A poor choice by the female has much greater repercussions on her fitness than a similar poor choice by a male has on his fitness (Orians 1961). Based on this, Weatherhead and Robertson (1979) proposed the sexy son hypothesis, which is one of several possible explanations for the highly diverse and often astonishing ornaments of animals (Mead and Arnold 2004). If females choose physically attractive males, they will tend to get physically attractive sons, and, thus more grandchildren, because other choosy females will prefer their attractive, sexy sons. The theory will work regardless of the physical or behavioral trait a female chooses, if it is heritable (i.e., the trait varies between individuals of the population), because it is possessing the trait that makes males attractive, and not the qualities of the trait. Once a preference becomes established, females choosing males with elaborate secondary sexual traits will produce sons that carry alleles for the trait and daughters that carry alleles for the preference, generating genetic coupling that will drive self-reinforcing coevolution of both trait and preference, due to the mating advantage of males with the trait, creating a runaway selection sexy sons process (Mead and Arnold 2004). Similar models have been proposed for postcopulatory female preferences, such as the time at which females removed the male's sperm ampulla after mating. Sexual selection by direct and/or indirect benefits as well as sexual conflict determines the evolution of animal mating systems (Andersson and Simmons 2006). In its original context, the "narrow-sense sexy son hypothesis" of Weatherhead and Robertson (1979) refers to mating systems with care from both parents. In these

mating systems, females that mate with a polygynous male normally receive less assistance than females that mate with a monogamous male (Ligon 1999), and thus suffer from direct fitness consequences that must be (at least) compensated for by the breeding successes of their sexy sons. On the other hand, a "broad-sense sexy son hypothesis" encompasses both polygyny and promiscuous mating systems, with and without care from both parents. Alatalo (1998) argues that the costs of any additional choice may be so minor that female choice for honestly signaling males, that is, good genes, may evolve even if the indirect benefits on offspring quality are small. A similar argument can be made for the sexy son hypothesis if mates of attractive males do not suffer any direct fitness consequences (Huk and Winkel 2008).

In summary, Weatherhead and Robertson (1979) propose a model of the evolution of polygyny in which female choice of mate is at least partially determined by male "sexiness" characteristics that are advantageous only because they attract females.

Conclusion

The sexy son hypothesis claims that females are assumed to compensate for the survival of their offspring by increasing the number of descendants produced. It provides another insight into investigating human being's mate selection strategy based on the evolutionary psychology.

Mate Value

James Malcolm Howie and Andrew Pomiankowski
University College London, London, UK

Synonyms

Mate worth; Partner reproductive value; Potential mate or partner fitness value

Definition

The “mate value” of a potential mating partner is the inclusive fitness gain that a focal individual makes from mating or partnering with that individual; also, in humans, it is the value of prospective partners on the “mating market.”

Introduction

Mate value is the total potential fitness value to be gained from a prospective mate or partner. It includes all aspects of fitness, incorporating a mate’s phenotypic condition, genetic quality, and resource holding. These factors must be evaluated as to how they affect the fitness of the chooser; for example, given variation in the chooser’s resource holding or genetic compatibility. It is expected that individuals will be selected to maximize the mate value of their partners, leading to the evolution of the criteria used in mate choice. As it is unlikely that mate value can be directly assessed, it must be inferred from morphological and behavioral traits, which evolve under the selective pressure of the choosers choices. This leads to the evolution of traits that reveal mate value, as well

as to counter-selection for the ability to amplify apparent mate value. In animals, plants, and even unicellular organisms, assessment of mate values involves a variety of sensory abilities that enable discrimination between mates. In “higher” animals, it has also been suggested that the evolutionary assessment-advert feedback was critical to the evolution of cognitive capacities, complex social behaviors, and even human language, rendering mate value a pervasive and important area of investigation.

Here is presented an outline of the component aspects of mate value, how they can vary over time, and how the relative value of each component can depend on specific attributes of potential partner pairs. After this, a wider view is taken, explaining sex differences in mate value, and the role of mate value in social species, human interactions, sexual selection, social evolution, and the evolution of human psychology, cognition, and language.

Aspects of Mate Value and Its Variation

Mate value includes all aspects of fitness that can be imparted, and is thus similar to the broad-sense attractiveness of an individual as a potential mate (Buss and Shackelford 1997; Gangestad and Simpson 2000; Edulund and Sagarin 2014). In humans, mate value is sometimes considered in narrower terms as “the extent to which mating with ... *and retaining* ... a partner would have increased a ... person’s ancestral reproductive success” (Sugiyama 2005). In fact most work on “mate value” conducted in humans has used this narrow sense, while that in animals has used the wider concept of “reproductive value”. Yet the areas are not disparate, and a more serious effort to unify them would be useful.

A list of mate value fitness attributes would include the condition of an individual in relation to its environment (e.g., its fat reserves, disease status), the quality of the individual in terms of its genes (e.g., “good genes,” level of heterozygosity), the quality of the individual’s current resources (e.g., territory size, nest site), and their capacity to hold them over the reproductive period and contribute to the fitness of the chooser (e.g.,

the individual’s resource holding potential, age, capacity to provide parental care) (Gangestad and Simpson 2000). These attributes of mate value are valued by a chooser in as far as they will increase its current or future fitness. Finally, in a human-specific sense, mate value can also incorporate more subtle traits, including the “Big Five” personality traits: openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism, as well as complex attributes such as trustworthiness, social status, or aspects of wealth, in relation to the trait-state of the perceiver (Goldberg 1993; Edulund and Sagarin 2014). This list could be extended ad nauseum to cover the particular life history details of a species or the intricacies that surround human social and cultural values. What matters from a biological viewpoint is how the survival and reproductive output of the chooser (and that of their offspring) is improved by the mate choice value they ascribe to potential partners when choosing a mate.

In addition to these traits, which are mate value indicators of signaler quality, it has been widely recognized that attractiveness per se can be a feature of mate value. This came out of one of the first attempts to model the evolution of animal and human aesthetic appreciation, by the statistician and geneticist Ronald Aylmer Fisher in the 1930s (Andersson 1994). Fisher saw that arbitrary sexual preferences could be evolutionarily self-reinforcing, because the trait preferred would be inherited by offspring along with the preference itself, coupling the evolution of ornament size and preference intensity. This force – the so-called self-reinforcing Fisherian runaway – may explain the bewildering diversity of sexual signals used in nature – which are often the only obvious traits that differ between closely related species. What remains unclear is why some mate value traits are stable whereas others turn-over. For example, species of peafowl related to the renowned peacock all have exaggerated tail feathers, but differ in coloration. There are parallels here to the diversity of cultural ornamentation and display found in human populations. It has been suggested, for instance, that courtship traits that have high mate value persist whereas those just serving as attractants are subject to rapid change. This explanation

fits both for changes over evolutionary time in animal species and cultural change in human courtship traits, where it could be the case that being fashionable is the true mate value.

Each of these aspects will be discussed in various contexts below. But it is first important to make the general points that (1) the rating of different parts of an individual's mate value may vary over their lifetime (for example, a female may become more or less fertile with age); (2) that what is, or is not, important in mate value varies among species, mating systems, and across the sexes (for instance, a male may value different attributes of a partner to a female); and (3) the mate value of an individual can be relative to that of the set of competitors or potential partners (a "large" male in one context may be "small" in another; the value of two individuals as partners can depend on their compatibilities).

Mate Value in Mate Choice: Perception and Reflection

A female or male will benefit their inclusive fitness if they mate, or partner, with an individual of the opposite sex with a high mate value: either from direct benefits (for instance, nuptial gifts, or parental input) or indirect benefits to their offspring (such as "good genes," heterozygosity, or "sexy genes") (Andersson 1994; Roberts and Little 2008). Given this, it is in the interest of high-value individuals to signal their quality, for instance through high cost, condition-dependent sexual ornaments, or handicaps (Andersson 1994). This increases the chances that they will be chosen as partners. It allows them to be distinguished from lower value individuals who cannot signal in the same way without incurring punitive costs to their survival chances (Pomiankowski 1988). With handicap signals, individuals signal their quality "honestly" allowing the chooser to discriminate and obtain the highest value mates, albeit within the constraint that errors occur as choosers are always to some degree limited in their abilities to make assessments and to detect cheats (Andersson 1994). A consequence is selection for traits associated with discrimination and

perception, such as visual and auditory senses, or even more complex neurocognitive traits, for instance when "ornament traits" involve aspects of intelligence.

Another consequence of the desirability of high-value mates is selection for self-reflexive perception and discrimination. All individuals "want" to maximize their own fitness and seek to mate, or partner, with high mate value individuals (Andersson 1994). But, the quality of partner an individual can obtain will be relative and dependent on others with whom they have to compete. It is a waste of resources – both in energy and time, and sometimes in risk – to seek partners with unobtainable mate values; for instance, for a low-value male to seek access to a high-value female, if she has the opportunity to be choosy, or vice versa (Andersson 1994). A high-quality individual might therefore "want" to behave differently to one of lower value, becoming choosier, or more promiscuous (dependent on its sex and mating system) (Andersson 1994). Likewise, if compatibility is important, then, in prospecting for potential mates, an individual will "want" to account for aspects of itself (Mays and Hill 2004; Buss et al. 2017). In both cases, the tools used for discrimination and assessment, which are used to make an external choice of partners, may be turned inward and provide a basis, consciously or not, for the assessment of self. While the evolving traits will depend on species, sex, and mate system, the search for high mate value partners will feed back on itself and so play a role in driving the evolution of complex behaviors and cognitive capabilities.

Sex Differences: What Males and Females Want

The two sexes are fundamentally distinct due to differential selection either for numerous, small, motile gametes (sperm) or for few, large, static gametes (eggs) (Beukeboom and Perrin 2014). This gamete dimorphism is absent from unicellular species, but almost universal amongst multicellular forms. It is widely believed that sex differences flow from this number-nutrient distinction, and

lead on to differences in what constitutes mate value in the two sexes (Andersson 1994). A demonstration of this can be found in an iconic experiment carried out by Bateman (1948), on the fruit fly *Drosophila melanogaster*. He allowed males and females to mate multiply and showed males had much higher variance in reproductive success than females. Male reproductive success increases with each mating as this results in more fertilization, whereas female output is limited by the resources available to invest in eggs, rather than the number of times she mates. The implication is that, because male sperm are cheap relative to female eggs, males seek to maximize their mate and offspring numbers, while females choose amongst potential partners in order to maximize the quality of each of their offspring. Although there are notable exceptions – such as sex-role-reversed sea horses (where males carry out the work of parental care) – this number versus quality rule holds out over a wide range of species including insects, fishes, amphibians, reptiles, birds, and mammals (Beukeboom and Perrin 2014).

The translation of this rule into mate value is complex, including many species-specific factors, but is dominated by the mating system of the species in question. For example, in a promiscuous mating system, in which males do not contribute parental care or any resources, a female only gains sperm from a male. Hence, male mate value relates primarily to aspects of a male's genetic quality or attractiveness, as exemplified by the peacock's train or stalk-eyed fly eyestalks, and by material or mental constructions, such as the bower bird's decorated maypole and avenue structures (Andersson 1994) or even human conversational ability (Fitch 2010). In these cases, the male is largely indiscriminate and simply assigns all females a similar mate value (Andersson 1994). In male-dominant systems, typified by the elephant seal or red deer, females largely let male fighting determine which males are potential mating partners, which presumably presorts male genetic quality. Females avoid consorting with subdominant males in order to avoid dangerous conflicts, in order to minimize the costs of mating (Andersson 1994). However, male discrimination has been demonstrated within these systems, as

males can attract or herd several females and cannot necessarily mate with all of them in the same time period. For instance, in stalk-eyed flies, males show a burst of sexual activity at dawn, and evaluate female mate value associated with size and so fecundity, mating first with large females when they have a choice.

Alternatively, the mating system can be more sex-balanced leading to much less difference in male and female reproductive success. In the extreme, there is pair bonding, and both parents contribute equally to parental care. Here, the distinction between male dominance and female choice is far less apparent. Females value males in relation to their condition, and how this predicts parental care (Andersson 1994; Trivers 1972). Males value female condition for the same reasons. Indeed, many examples are known where male and female indulge in mutual mate choice, using ornaments and behavior equally in their courtship displays, as in the albatross (Andersson 1994, Trivers 1972). However, extra-pair copulation can result in greater fertility for males and trade-up genetic quality in females, or other more subtle fitness gains (e.g., outbreeding, avoidance of neighbor aggression), so even within monogamy, subtle differences may persist in male and female mate value.

Sex Differences: What Men and Women Want

Human mating systems are complex and highly variable, but can be characterized, roughly, as serially monogamous, with individuals paired in one or more semiexclusive long-term relationships across a lifetime, with extra-pair copulation more or less present, and phases of polyandry and polygyny common in some cultures (Buss and Schmitt 1993; Gangestad and Simpson 2000). The recent emergence of easier birth control may have permitted greater levels of promiscuity by both sexes (Gangestad and Simpson 2000). Females are often the choosier sex, although males also exert notable choice. Because human mating systems vary across cultures and over time it is difficult to make unifying claims about mate

value and mating system (Gangestad and Simpson 2000). However, there are several reasons to believe that the sort of systems outlined above held true across much of human evolution (Simmons et al. 2004). Human men tend to be larger than human women, that is, humans are sexually dimorphic, which implies sexual selection, with potential roles for female and male choice. Further, men have large testes and produce large ejaculates relative to many primates, indicating that sperm competition was historically common (Simmons et al. 2004). Finally, cross-cultural records and observations show that variants on serial monogamy with extra-pair copulation are, and were, common (Buss and Schmitt 1993; Marlowe 2003), with extreme exceptions, like the “reproductive factories” of the ancient Chinese Imperial Harem or the Ottoman Grand Seraglio intermittently observed (Pinker 2011).

Humans also fit with Bateman’s observations. Men produce large numbers of sperm, and can father 10s, 100s, or even 1000s of children, for example, in the famous cases of Gengis Khan and Ismail ibn Sharif (Zerjal et al. 2003; Oberzaucher and Grammer 2014). In contrast, lifetime reproduction by women is at most in the 10s of children; the current record is held by the Russian Mrs. Feodor Vassilyev, with 69 (Urban 1783). In fact, the averages for total and intersex variation in reproductive output are far lower than these maxima (with means nearer 1–3 children and variance around 1–5 in most modern cultures studied, van Daalen and Caswell 2017, and modest differences between men and women, Brown et al. 2009), but this information can still be informative about mate value.

At a broad stroke then, the traits *expected* to count in women’s assessments of men, when looking for long-term partners, include those associated with a man’s ability to provide parental care, such as his condition, wealth, rank and mental disposition, and with traits associated with his resources, genetic quality, and physical attractiveness (Trivers 1972; Buss and Schmitt 1993). In contrast, attributes counted in women’s assessments of men as short-term or extra-pair partners should relate more directly to a prospective male partner’s genetic quality and attractiveness, or

to additional advantages presented through gifts, wealth, or social connections, with little concern given to direct parental input (Buss and Schmitt 1993; Gangestad and Simpson 2000). Likewise, mate value assessments made by men looking for long-term female partners should relate primarily to traits associated with a woman’s ability to produce and rear healthy children, such as her condition, age, and overall genetic quality (Buss and Schmitt 1993), or related to her attractiveness, though traits such as “curviness,” which may be associated with fecundity. In contrast to assessments made of men by women, however, men’s assessments of women as short-term or extra-pair partners should still be based on estimates of the women’s capacity to produce offspring and provide maternal care (Trivers 1972; Buss and Schmitt 1993). The reason for this sex difference is that additional reproduction is more costly for women. In most cultures, women contribute more to raising children than do men (and must always give birth). If a woman is to have a short-term or extra-pair partner, genes or gifts are required; a man requires only a partner, and can then leave (Andersson 1994; Trivers 1972; Buss and Schmitt 1993; Gangestad and Simpson 2000).

In line with this, recent large-scale cross-cultural studies have found that single women do indeed prefer men exhibiting traits such as wealth, generosity, intellect, dominance, cultivation, sociability, reliability, similarity, kindness, understanding, humorousness, and pleasantness as potential long-term or marriage partners, while single men prefer women who are attractive, creative, and domestic (Schwarz and Hassebrauck 2012). Further, while women will consider long-term male partners 5 years younger to 8 years older, men will consider female partners 10 years younger but only 4.5 years older (Schwarz and Hassebrauck 2012). Finally, women are also less likely to consider an opposite-sex partner for marriage if the individual earns less, is less educated, or is irregularly employed, but are more likely than men to consider a less-attractive opposite-sex partner for marriage (Schwarz and Hassebrauck 2012). However, these observations have only been made in a limited set of cultures and

environments, and may not be as general as is usually assumed.

Additional studies have shown that predicted patterns also follow within relationships. Partnered women are more likely to prefer extra-pair partners with more “masculine” faces, symmetry associated scent, deeper voices, and other behavioral displays associated with intrasexual competitiveness (Gildersleeve et al. 2013), while partnered men focus more on traits like attractiveness and youth, associated with fertility and fecundity (Roberts and Little 2008). An important point though is that in each case, the traits preferred by men and women vary with self-assessment, such as that reflected in self-esteem, self-assessed quality, or complementary mentalities (Roberts and Little 2008; Reeve et al. 2017). A clear demonstration of this relative-to-self mate value is that female mate preferences have been shown to vary with the menstrual cycle. This cycle causes a fluctuation in female mate value, which increases near ovulation, but is very much reduced postmenses. Complementing this, there is temporal variation in female mate preference as a female approaches ovulation, with increased interest in “masculine” traits (Roberts and Little 2008; Gildersleeve et al. 2013). Mate-value feedback plays a role here too, as a female’s awareness of her own reflected mate value – conscious or not – will be crucial to her behavior (Roberts and Little 2008; Reeve et al. 2017). Another example of relative-to-self mate value, for instance, is the finding that women become less choosy after rejection (Reeve et al. 2017), with an accompanying drop in their levels of self-esteem (Schwarz and Hasselbrauck 2012). Likewise, men’s assessment of their own mate value is linked to their partners mate value and influences their self-esteem and retention behaviors (Starratt and Shackelford 2012; Holden et al. 2014). Men with higher self-esteem do more provisioning behaviors, give fewer negative comments and commit less violence, but can be more likely to cheat – as too can women with higher self-esteem and components of mate value (Starratt et al. 2017). All of these behaviors arise though selection for self-perception and the constant assessment of relative mate value. They shape human psychology, playing a crucial role in

influencing the evolution of phenomena such as mate switching and partner fidelity (Buss et al. 2017; Starratt et al. 2017).

In short, as is theoretically expected, women appear to be interested in and to value men in relation to their intelligence, mentality, wealth, and resources, while men value women as mates more in relation to attractiveness, youth, creativity, and domesticity, with variations in the targets and intensity of preference arising in line with partnership status and mate value fluctuations.

Mate Value in Social Evolution

An important class of mate value traits, for animals and humans, are the context-dependent mental traits associated with society and socialization. Forms of society are exhibited by animal classes as diverse as ants, bees and wasps (the eusocial insects; discussed elsewhere in this volume), crows and parrots, dolphins and elephants, monkeys, apes and humans (Whiten and van Schaik 2007). In each case, the social environment influences mate value. A simple near-universal instance, touched upon above, arises from rank or social status. Rank is a social construct, but its consequences are very real. High rank can be inherited by birth, or can emerge from physical strength, or from aspects of intelligence such as the capacity to make alliances or manipulate other members of the social group to obtain “political” power (Chapais 2015). When rank differences are pronounced, they confer advantages to those with higher rank, including but not limited to, better access to resources, reduced stress, reduced effort in food searches, and increased access to sex and reproduction (Rodriguez-Llanes et al. 2009). So rank itself tends to increase an individual’s mate value.

This observation applies to all animals, including humans. In the case of monkeys and apes such as macaques and chimpanzees, rank can be comprised of strength, alliances, and birth, as signified by behavior (Rodriguez-Llanes et al. 2009). In humans, rank is a less concrete trait (Chapais 2015). It comprises traits such as “political” power, wealth, and positional power (e.g., in a work place) (Chapais 2015). All traits associated

with this rank-power will be selected via mate choice, and all traits that assist in obtaining rank-power will also be selected. This is an example of socially context-dependent mate value. Others include the ability to make friends, form alliances, or manipulate individuals/groups (Brent 2015).

Mate Value and Mental Evolution: Cognition, Language and Deception

As can be seen, the need to assess mate value between prospective human mate partners has the potential to enhance discrimination, both through physiological and neurological mechanisms. Moreover, as mate value will be in part determined and assessed in a social context in human societies, it has been suggested that it has contributed to the evolution of mental capacities, including the ability to make accurate self-assessments and to detect inaccurate and deceptive displays of mate value (Shettleworth 2001; Whiten and van Schaik 2007). For instance, as soon as language or proto-language evolves, it is plausible that linguistic ability becomes a mate value focus, similar to how bird and whale song are included in mate value assessments (Fitch 2010). While linguistic ability, like vocabulary, originality, or construct complexity, could be condition-dependent traits used to assess mate value, language could also be used to exaggerate claims about the self, and induce high-value partners to mate (Fitch 2010). The consequence should be selection for better abilities to detect such deception and to direct mate value assessment toward honest expressions of quality, possibly leading to various selective feedback loops leading to better abilities in both language and intelligence (Fitch et al. 2010). In this way, mate value may have played a role on the evolution of human language, cognition, and psychology, but this remains to be fully tested.

Conclusion

Mate value is the total value of a potential mate to the current, future, or inclusive fitness of an individual that is assessing prospective mating

partners. Which traits contribute to mate value will depend on species, mating system, and sex. Further, mate value will vary over an individual's life, and in relation to the current state, situation, or context that an individual is in. Mate value can influence mate choice, social interactions, and behaviors. It must play a crucial role in sexual selection and social evolution. Moreover, selective feed-back between choosers and chosen mean that mate value assessment will have important consequences for the evolution of intelligence, psychology, cognition, and, at last, human language. Looking to the future, it would be useful to more fully integrate across narrow human mate value studies and the wider reproductive value ideas used in animals. This will bring new insight.

Definition

Mate value inflation is the process of employing strategies to increase one's value as a potential mate by targeting characteristics preferred by the opposite sex, making oneself more desirable so as to increase the chances of successful mating.

Introduction

Over the course of evolutionary history, characteristics that enhanced survival or held reproductive value were preferred when searching for potential mates (Buss and Schmitt 1993). Possessing these characteristics, therefore, was indicative of one's mate value and allowed one to be successful in the game of sexual selection.

The current chapter reviews the mate preferences of men and women, discusses the strategies men and women engage in to enhance mate value, and highlights some of the consequences that may result from mate value inflation in the context of modern social media.

Evolved Mate Preferences

Men and women evolved to prefer different characteristics in a mate as a result of different adaptive challenges they faced in the ancestral past. Due to women's decline in fertility as a function of age, men tend to look out for traits indicative of high reproductive value and sexual desirability such as physical attractiveness (Buss 1989). In contrast, men offered resources and protection which aided the survival of women and their offspring; hence, women tend to look out for men's social status and industriousness, traits which are ancestrally related to their ability to provide resources and their physical strength (Buss 1989). With these key dimensions being sought after by a big pool of intrasexual competitors, individuals would have to possess a sufficient level of mate value to be selected by members of the opposite sex for mating and reproduction.

Mate Value Inflation Strategies

Mate value is determined by one's possession of the key traits that the opposite sex has evolved to value and prioritize in their mates, and the amount of resources – time, money, and effort – one is willing to expend during the mating process (Fisher et al. 2008). Displaying high mate value facilitates success in the mating game as high mate value attracts potential mates, provides mating opportunities and the option of choosing higher quality mates among a pool of potential mates, and enhances one's position in intrasexual competition (Yong et al. 2016). Thus, with the many benefits high mate value confers, both men and women engage in behaviors that serve to

increase their chances at reproductive success. Strategies that serve to inflate one's mate value are primarily aimed at enhancing the key traits sought after by the opposite sex.

Physical Enhancements

Women, more than men, are likely to enhance their physical appearance (Buss 1988; Buss and Schmitt 1993). They consume diet pills (Hill and Durante 2011), sign up for and attend artificial sun-tanning sessions (Hill and Durante 2011), and undergo cosmetic surgeries (Arnocky and Piché 2014) to enhance their attractiveness despite the negative health repercussions and risks associated with such methods. Women also allocate a larger portion of their financial resources than men to buying appearance-enhancing beauty products (Hayhoe et al. 2000) and continue to do so even when economic times are bad (Hill et al. 2012). In doing so, females portray themselves as more attractive so as to target males' evolutionary preference for physically attractive mates.

Conspicuous Consumption

Owning luxury products also serves to inflate mate value as it signals to potential mates that preferential mate traits are present (Griskevicius et al. 2007). Conspicuous consumption is dominantly used by men to draw attention to their social status and wealth – indicators of resource abundance – which are characteristics that women have evolved to seek (Sundie et al. 2011). Women also seek to own luxury products in efforts of promoting their mate value (Hudders et al. 2014). Women who own luxury products are perceived to be more attractive by other women, and hence are perceived to have higher mate value. This gives women an advantage over their rivals, particularly those who own less luxurious products, in intrasexual competition.

Conspicuous spending on altruistic causes also aids in the enhancement of mate value. In recent times, there has been an increase in spending on products that are perceived to be "green." Because altruistic behaviors that displayed humanistic and moral attitudes suggested better genes and demonstrated ideal mate traits such as good parenting habits (Cela-Conde et al. 2010), spending on such

products are indicative of an individual's willingness to partake in pro-social behaviors over pro-self-behaviors, thus elevating one's mate value. Additionally, individuals are more inclined to make purchases of "green" products only when costs incurred are higher than or equal to their nonenvironmentally friendly counterparts, and when the purchases are done in public (Griskevicius et al. 2010). This display signals that they have enough resources to "give away" without inflicting financial loss (Griskevicius et al. 2010). Thus, conspicuous consumption on both luxury and "green" products is suggestive that an individual possesses ideal mate traits of resource abundance, and arguably, altruism, making displays of such consumptions a fitting way of increasing one's perceived mate value.

Mate Value Inflation Through Social Media

Individuals can also enhance their mate value on social media through technological tools and features offered on these platforms. Less attractive individuals are likely to increase their physical attractiveness with more flattering photos, or older photos in which they look younger, and are also more likely to be deceitful in verbally describing their looks (Toma and Hancock 2010). Additionally, women are more likely than men to have doctored photographs online (Hancock and Toma 2009) and to misrepresent personal characteristics such as their age and weight (Hall et al. 2010). In contrast, men, more than women, strategically misrepresent characteristics such as personal assets, personal interests, and personal attitudes on their online dating profiles (Hall et al. 2010).

With social media, signaling attempts of mate value, where once displayed in natural real-life settings, can now be displayed virtually to a much larger audience than possible during ancestral times. This is especially useful since social media is increasingly being used as a platform for seeking mating opportunities. For example, a study observing conspicuous displays of exercise efforts found that the act of posting workouts

served to inflate one's mate value, tapping on mate preferences for healthy individuals (Vandenbroele et al. 2019). Similarly, signaling efforts in conspicuous spending and consumption, where the outwards display of wealth as an ideal mate trait influences mate value, are more easily displayed through social media.

Consequences of Mate Value Inflation Strategies

Engaging in mate inflation strategies such as those outlined above brings about an array of consequences beyond that of a higher mate value. Mate inflation strategies implicate deception, which is defined as the consequence of an individual's attempt to send signals that specifically appeal to the preferences of the opposite sex (Buss and Schmitt 1993). More often than not, individuals misrepresent their actual mate value in their attempts to inflate their mate value. Women experience higher emotional distress upon being deceived about a mate's resources or social status (Haselton et al. 2005). On the other hand, men – being the sex more invested in short-term mating – experience greater emotional distress than women when sexually deceived, especially when they are misled by a potential partner about their willingness to have sex (Haselton et al. 2005).

Using the tools and nature of social media to inflate mate value also invites several less-than-desirable consequences, especially with social media being a mate-searching platform. Increased access and exposure to potential mates through social media and dating platforms have caused excessive searching due to the massive number of choices available (Yang and Chiou 2010). Excessive searching refers to the search for the best available option among potential mates available online, ultimately resulting in worse mate-choice decision-making (Yang and Chiou 2010). Furthermore, access and exposure to a larger number of attractive individuals reduces males' likelihood to remain committed to existing mates and reduces females' self-perceived desirability (Kenrick et al. 1994). Positive interactions with potential mates on these platforms, such as

receiving likes, swipes, or matches, can lead to an inaccurate sense of self-perceived desirability and increased intentions of infidelity (Alexopoulos et al. 2019).

Conclusion

Humans engage in mate inflation strategies to make oneself more desirable to potential mates and to, ultimately, boost chances of successful mating. These strategies typically revolve around enhancing the key traits sought by the opposite sex – resources and status in men by women and physical attractiveness in women by men. Social media – which increasingly offers mating opportunities – allows quick, low effort displays of conspicuous consumption and enhanced physical appearances, hence adding on to the repertoire of strategies one can engage in to enhance mate value. However, mate value inflation strategies bring about deception attempts, which lead to emotional distress in both men and women. Inflating mate value online also leads to poor decision-making in mate choice and reductions in partner commitment and fidelity.

Maternal Abandonment and Maternal-Fetal Conflict

Jennifer Kotler

Harvard University, Boston, MA, USA

Synonyms

[Infanticide](#); [Neglect](#)

Definition

Withdrawal of maternal caring behaviors after the baby is born; may directly or indirectly lead to infant death.

Introduction

Evolutionary conflict occurs when natural selection acts in opposing directions on different genes involved in an interaction (Burt and Trivers 2008). Conflict can be found at all levels of organization, from conflict between species, to conflict between individuals within a species, to conflict within an individual itself. Most of these forms of conflict revolve around competition for resources and differences in optimal resource allocation among individuals. Between genetic relatives, what is beneficial to one relative may not be beneficial, and may even be detrimental, to another. This situation occurs when there is an unequal probability that genes from one individual will be shared with another. For example, if a mother invests abundant resources in one child, it benefits both that child and, due to shared genes, the mother herself; however it will detract from the mother's ability to invest in other offspring. From the maternal perspective, she shares half her genes with each of her children, so she benefits optimally from maximizing her reproductive output. However, from the perspective of any one child, there is a lower probability that a gene found in that child's genome will be present in other siblings (although there is a 50 % probability that a maternal gene found in one sibling will be found

in the other, the sibs may not be paternally related, thereby reducing their probability of genetic similarity) (Trivers 1974). Therefore there is an unequal benefit for the child relative to the mother when she allocates resources to any one child versus conserving resources for other potential offspring. These situations produce what is known as maternal-offspring conflict.

While the loss of a child will result in a perceived fitness cost for the mother, there are situations in which the long-term fitness benefit will compensate for this initial cost; however this will always come at a cost to the genes present in the child. From mum's perspective, it is better to invest fully in a future reproductive event than to invest in an offspring that is unlikely to succeed. This is most commonly seen in spontaneous abortion, as the earlier the mother stops investing in the child the lower the cost will be to her. However this can be a tricky process, because after implantation the offspring is able to take some control over its own fate (see ► [Spontaneous Abortion and Maternal-Fetal Conflict](#)). After birth the power shifts substantially back into the hands of the mother. Furthermore, in a uterine environment it can be challenging for a mother to accurately assess the quality of her potential offspring, as there are many situations that would be severely detrimental to a child after birth that would not be apparent in utero (e.g., it is difficult to test for blindness in the womb). For these reasons maternal rejection, abandonment, or even infanticide can occur after birth.

Infanticide

In humans, the majority of infant deaths due to injury are caused by homicide. Infant homicide in the first 3 years of life is most commonly committed by an unrelated person, but during the first year of life the mother commits most infant homicides (Overpeck et al. 1998). In fact, it is estimated that over 80 % of all babies killed will die in their first day of life (Bradley 2003), usually at the hands of the mother (Hrdy 2016). There is a ten times greater risk of neonaticide (homicide in the first day of life) than at any other time in life (Herman-Giddens et al. 2003). In one

study of newborn homicide (0–4 days of life; death due to homicide or abandonment) in the USA, mothers were responsible in over 85 % of cases, with the age of the mother ranging from 14 to 35 years, and 35 % of cases occurring in second or subsequent pregnancies (Herman-Giddens et al. 2003). This indicates that, while there are many risk factors of early infanticide, it happens with a broad range of women, often after at least one successful pregnancy has already occurred.

Rates of infanticide increase with economic stress (Hatters Friedman and Resnick 2007), with the USA exhibiting higher rates of filicide (parents killing their own offspring) than any other developed country (Friedman et al. 2005). While older mothers who commit neonaticide are more likely to be psychotic, neonaticide is more often committed by young mothers without many resources or access to help with caregiving (Friedman et al. 2005). In other cooperatively breeding primates like tamarins, mothers are significantly more likely to abandon an infant if she has no help, with most abandonment decisions occurring within the first 72 h after birth (Bardi et al. 2001). This appears to support the evolutionary expectation that a mother is best off cutting her losses as early as possible, especially when she has fewer resources available.

In less extreme circumstances, behaviors that are intended to elicit maternal care in healthy infants, such as crying, are evaluated differently by mothers in response to cues of low health. Some ethnographic reports describe maternal aversion to cries of sickly seeming infants, while cries in fat, healthy looking babies are met with maternal attention (Hrdy 2016). In an experimental paradigm, adults rated faces of babies that had been artificially manipulated to appear skinny (low subcutaneous fat) as less cute and less healthy, and even showed decreased adoption preferences in response to the manipulation (Volk et al. 2005). These results indicate that mothers assess infant health, consciously or subconsciously, and may be weighing the cost of maternal response against the probability of infant survival.

Postpartum Depression

Postpartum depression (PPD) is the onset of clinical depression after delivery of a child. It is quite common, affecting about 15 % of women (Robertson et al. 2004) in cultures all around the world (Tracy 2005). “Baby blues,” a less severe version of PDD which begins within days of delivery, is significantly more common, affecting up to 75 % of mothers (Robertson et al. 2004). Symptoms of PDD can include withdrawal from maternal care behaviors, the most extreme cases of which can result in infanticide (Robertson et al. 2004). Evolutionary psychologists and anthropologists have theorized that PPD evolved as part of the mechanism for allowing mum to decide on the degree of investment to make in a given offspring (Thornhill and Furlow 1998). It may also be used as a signal to increase alloparental support (Tracy 2005); one of the most common risk factors for postpartum depression is perceived lack of support (Tracy 2005), so exhibiting symptoms of PDD may be an adaptive response for soliciting support from family members.

Infant Countermeasures

Although an infant will be genetically related to a future sibling, it is always most related to itself; therefore it is selected to favor its own survival over that of a future potential maternal sibling. It is hypothesized that many traits commonly found in human babies have evolved in order to acquire maternal attention and resources, and reduce the likelihood of being abandoned (Hrdy 2007). These include the extremely high levels of subcutaneous fat that we acquire shortly before birth (Cunnane and Crawford 2003) and a variety of behaviors for eliciting maternal engagement (Hrdy 2007). For example, human babies have much larger sclera (whites of the eyes) than other primate babies. This has been described as an evolved mechanism to elicit maternal care, as it highlights the direction of the infants’ gaze (Hrdy 2007). Not only are features such as round eyes and chubby cheeks perceived as “cuter,” they

have also been shown experimentally to elicit caregiving behaviors relative to photos of infants digitally manipulated to lack these features (Glocker et al. 2009a). These characteristics of infant faces have been shown experimentally to modulate the mesocorticolimbic system, including the nucleus accumbens (reward anticipation), striatum (mutual cooperation and social bonding), and precuneus (attention focusing) (Glocker et al. 2009b).

In addition to these physical features, human infants smile, laugh, and imitate adult facial expressions in ways not observed in other newborn apes (Hrdy 2007). Evidence for the role of genetic conflict here can be found in the literature on Prader-Willi syndrome (PWS) and Angelman syndrome (AS). Individuals with PWS are missing a paternally expressed component of chromosome 15, and are described as weak, quiet, and sleepy (Haig and Wharton 2003). On the other hand, individuals with AS are missing the maternally expressed component of the same chromosome, and these individuals demonstrate increased signals of social engagement, such as frequent smiles, laughter, and sustained eye contact with caregivers, specifically in the presence of other children (Brown and Consedine 2004). This has been interpreted as indicating that, when unopposed, maternal genes benefit from decreased demands on the mother, while paternally inherited genes present in the child (but missing in the mother) elicit behaviors that are likely to attract maternal investment. This supports the notion that many traits found in infants have evolved to evoke increased maternal attention, bonding, and reward circuitry in the maternal brain in order to decrease the chances of maternal rejection.

Conclusion

Since pregnancy is such a costly process for the mother, there is increased pressure on mothers to invest in offspring that have already been born. That being said, there are markers of health and quality that are difficult to assess in utero. For this reason, there is still some degree of maternal-

offspring conflict after birth. While mum might benefit from limiting investment in a low quality offspring, baby would prefer to gain maternal investment even if that comes at a cost of future maternal sibs. This provides evolutionary pressure for adaptations in both mothers and infants to navigate this struggle.

Age of mother at birth of her child

Definition

Age of mother at birth of her child.

Introduction

Timing of parenthood varies strongly within individuals, across societies, and over time. Whether a woman gives birth to a child at ages below 20 or above 40 may have important implications for her well-being, as well as for that of her child. The process of postponement of parenthood has fuelled concerns about the implications of fertility postponement on the health of the children. There may, however, also be important benefits and advantages among those that are born to older parents. This article briefly reviews the characteristics of older mothers and current literature on both the potential positive and negative effects of older-age motherhood.

Characteristics of Older Mothers

A dominant demographic trend in the latter half of the twentieth century that has continued into the early twenty-first century has been fertility postponement and increasing age at first birth. For example, in Germany and the UK, the mean age at first birth exceeded 30 in 2009. In Sweden, the

share of children born to mothers over age 40 rose from 1% in 1975 to 5% in 2015; in the same period, the share of children born to mothers under age 20 declined from 8% to 1% (Human Fertility Database 2017). These processes have been attributed to the contraceptive pill, the expansion of career opportunities for women, and increasing economic uncertainty (Sobotka 2004).

The process of postponement has resulted in changing characteristics of older mothers. Historically, older-age parenthood has been associated with low socioeconomic status and high parity. However, this may have changed. Goisis et al. (2015) analyzed four UK birth cohort studies that covered 1958, 1970, 1992, and 2000–2002 and documented that in the 1958 and 1970 birth cohorts, socioeconomic status based on occupation and education was highest in the households in which the mothers were aged 25–34 years at birth. The pattern however was reversed in the later cohorts, as in the 1992 and 2000–2002 birth cohorts, socioeconomic status was highest in households in which the mothers were aged 35–39 at birth. Similarly, smoking while pregnant was high in all age groups in the early cohorts, but in the later birth cohorts, older mothers had the lowest rates of smoking while pregnant. These findings suggest that the sociodemographic disadvantage that historically was associated with older maternal age has not only disappeared but has turned into a potentially important advantage.

Maternal Age and Child Outcomes

A century ago, Alexander Graham Bell wrote that children born to older mothers have the shortest lifespan (Bell 1918), and a review by Liu and colleagues suggests that “Parental age has been shown to be a major factor, if not the most important factor, in producing variability in offspring”, including health, longevity, and intelligence (Liu et al. 2011). For example, the risk of negative birth and childhood outcomes – e.g., Down syndrome, childhood cancer, and autism – appears to increase with maternal age (Liu et al. 2011).

Moreover, existing literature suggests that being born to an older parent may also have long-term health consequences, and in particular, old-age mortality may be elevated among those that are born to older mothers (Smith et al. 2009).

There may, however, also be important benefits associated with being born to an older mother. Goisis et al. (2017) analyzed three UK data sets, covering the birth cohorts 1958, 1970, and 2000–2002, and found that while child cognitive development was negatively associated with maternal age in the early cohorts, in the 2000–2002 birth cohort, children that were born to mothers aged 35 and above scored higher than those that were born to younger mothers. Barclay and Myrskylä (2016) analyze Swedish data and find that being born to an older mother is associated with higher cognitive ability and higher educational attainment. An analysis of 77 countries across the world using the Demographic and Health Surveys suggests that the positive effect of being born to an older mother may not be limited to the rich world. In particular, in countries in which contemporary development is positive, being born to an older mother may be associated with decreased mortality risk at young ages (Barclay and Myrskylä 2017).

Maternal Age and Parent Well-Being

Parenthood may bring joy but may also come with unexpected stress, responsibilities, and challenges. Research on older mothers suggests that women who postpone childbearing are more “ready” and less stressed by having children (Gregory 2007). Using the World Values Survey data across a large number of countries, Margolis and Myrskylä (2011) document that the association between parenthood and subjective well-being depends on age, being negative at young ages, but reversing to positive at older ages (50+). Another study focusing on Germany and UK found that while having children mostly has only a temporary impact on subjective well-being, among those who experienced their first birth at ages 35 and above, the positive impact of

childbirth on the mother's well-being was long-lasting (Myrskylä and Margolis 2014). This suggests that the age at which individuals have their first children is a strong predictor of how much they are able to enjoy parenthood.

Conclusion

Although most research on advanced maternal age focuses on the risks associated with reproductive aging, recent research suggests that older mothers today differ from those in the past and that there are also benefits to postponing fertility to older ages. Older mothers today observe better health behaviors during pregnancy, are more socioeconomically advantaged, and seem to be happier after childbearing. Furthermore, the children of older parents in high-income countries have better health and educational outcomes.
